This often presents abruptly with a combination of synovitis and adjacent periarticular inflammation. It occurs most characteristically in the hands and feet, when synovitis of a finger or toe is coupled with tenosynovitis, enthesitis and inflammation of intervening tissue to give a 'sausage digit' or dactylitis (Fig. 25.42A). Large joints, such as the knee and ankle, may also be involved, sometimes with very large effusions.

Symmetrical polyarthritis

This form of PsA predominates in women and may resemble RA, with symmetrical involvement of small and large joints in both upper and lower limbs. Nodules and other extra-articular features of RA are absent, and arthritis is generally less extensive and more benign.

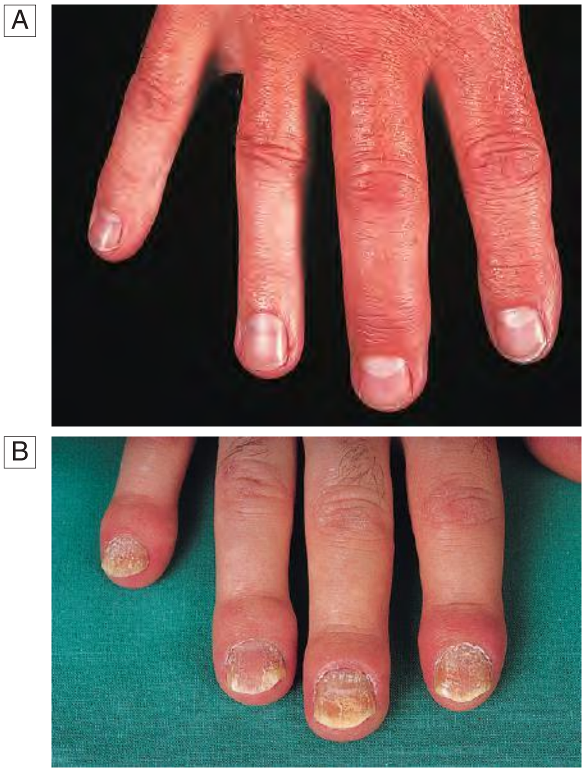

Fig. 25.42 Psoriatic arthropathy. **A** Dactylitis. **B** Distal interphalangeal joint pattern with accompanying nail dystrophy (pitting and onycholysis).

Distal interphalangeal joint arthritis

This is quite a common pattern. It can be difficult to distinguish from inflammatory generalised OA, but in PsA psoriatic nail disease is usually present (Fig. 25.42B).

Psoriatic spondylitis

This type presents with inflammatory back or neck pain and stiffness. Any structure in the spine can be involved, including intervertebral discs, entheses and facet joints. It may occur alone or with any of the other clinical patterns and is typically unilateral or asymmetric in severity.

Arthritis mutilans

This is a deforming erosive arthritis targeting the fingers and toes; it occurs in 5% of cases of PsA. Prominent cartilage and bone destruction results in marked digital instability. The encasing skin appears invaginated and 'telescoped' ('main en lorgnette') and the finger can be pulled back to its original length.

Enthesitis-predominant

This form of disease presents with pain and stiffness at the insertion sites of tendons and ligaments into bone (enthesitis). Symptoms can be extensive or localised. Patients often report the symptoms as muscle stiffness or aches. Typically affected entheses include Achilles tendon insertions, plantar fascia origins, patellar ligament attachments, hip abductor complex insertion at lateral femoral condyle, gluteus medius insertion at greater trochanter, humeral epicondyle tendon attachments, deltoid origin at acromial edge, intercostal muscle attachments at ribs, and pelvic ligament attachments. This form of PsA can be mistaken for fibromyalgia by the unwary.

Nail changes

Nail changes include pitting, onycholysis, subungual hyperkeratosis and horizontal ridging, which are found in 85% of patients with PsA and can occur in the absence of skin disease. The characteristic rash of psoriasis may be widespread, or confined to the scalp, natal cleft, umbilicus and genitals, or in areas where there are frictional skin effects (e.g. from clothing) where it is easily overlooked. Obtaining a history of psoriasis in a first-degree relative can be tricky but is important, given that a positive response contributes to making a diagnosis. Psoriasis and PsA may be discordant in the same individual, with onset of features sometimes years apart. The absence of psoriasis, or history of it, does not preclude a diagnosis of PsA (see Box 25.61).

Investigations

The diagnosis is made on clinical grounds. Autoantibodies are usually negative, though low levels of RF, ACPA and ANA can be detected, and acute phase reactants, such as ESR and CRP, are raised in only a proportion of patients with active disease. X-rays may be normal or show juxta-articular osteoproliferation or erosive change with joint space narrowing. Features that favour PsA over RA include the characteristic distribution (see Fig. 25.9), absence of periarticular osteoporosis and presence of erosions accompanied by new bone formation. Imaging of the axial skeleton, in advanced disease, can show coarse, asymmetrical, non-marginal syndesmophytes, juxta-facet joint osteoproliferation and sacroiliitis. MRI and ultrasound with power Doppler are increasingly employed to detect synovial inflammation and inflammation at the entheses.

Management

Patient education to understand the breadth, episodic nature and variability of disease is important. Weight loss may play a therapeutic role to limit clinical impact. Therapy with NSAIDs and analgesics may be sufficient to manage symptoms in mild disease. Intra-articular glucocorticoid injections can control isolated synovitis or enthesitis. Splints and prolonged rest should be avoided because of the tendency to fibrous and bony ankylosis. Patients with spondylitis should be prescribed the same exercise and posture regime as in axSpA. Therapy with csDMARDs should be considered for polyenthesitis or synovitis unresponsive to conservative treatment. MTX is the drug of first choice and is also effective for skin disease. Other csDMARDs may also be helpful, including SSZ, ciclosporin and LEF. Particular attention should be paid to monitoring liver function in patients treated with csDMARDs, since abnormalities are common in PsA. HCQ is not generally used in PsA but can be tried if other options are unsuitable. Anti-TNF-α should be considered for individuals with active inflammatory disease who respond inadequately to csDMARDs, and treatment is effective for both PsA and psoriasis. Ustekinumab, a monoclonal antibody that binds to and neutralises the p40 subunit of IL-12 and IL-23, improves joint, dactylitis and enthesitis lesions in PsA, has efficacy in treating psoriasis and nail disease, but is not used for axial disease. Ustekinumab is a useful treatment for PsA where there is associated IBD. The IL-23 inhibitors guselkumab and risankizumab are effective for the treatment of PsA but are not recommended for axial disease. The IL-17 inhibitors have greater efficacy than TNF-α inhibitors in PsA and are recommended for all aspects of PsA including axial disease and are particularly efficacious in skin disease. The JAKi DMARDs have similarly shown efficacy in treating all aspects of psoriatic disease. Apremilast (a phosphodiesterase-4 inhibitor [PDE4i]) is effective in PsA when NSAIDs and csDMARD therapy fails but seems to be less efficacious than bDMARDs and JAKi.

Enteropathic (spondylo)arthritis

The overall prevalence of inflammatory musculoskeletal disease in inflammatory bowel diseases (IBDs: Crohn disease and ulcerative colitis) is not well known, as studies have not adequately assessed enthesitis and osteitis lesions, but the musculoskeletal manifestations are in keeping with an SpA phenotype. Involvement of the peripheral joints is seen in about 20% of IBD patients. Oligoarticular disease predominantly affects the large lower limb joints (knees, ankles and hips). Evidence of sacroiliitis can also be detected by imaging in a proportion of patients with IBD. Imaging evidence of sacroiliitis is present in about 15%–20% of IBD patients. Osteitis pubis is also a typical lesion. In Crohn disease, more than in colitis, the arthritis usually coincides with exacerbations of the underlying bowel disease and the arthritis improves with effective treatment of the bowel disease. There is some suggestion that the severity and onset of inflammatory musculoskeletal symptoms can vary in association with changes in the integrity of the ileocaecal valve, raising the possibility that changes in gut flora may act as triggers for the associated SpA.

NSAIDs are best avoided, since they can exacerbate IBD. Instead, judicious use of glucocorticoids, SSZ and MTX may be considered. Liaison is necessary between gastroenterologist and rheumatologist with regard to choice of therapy. Anti-TNF-α therapy is effective in enteropathic arthritis, but etanercept should be avoided as it has no efficacy in IBD. Anti-IL-17 therapy should be avoided as it can trigger flares of IBD, but anti-IL-12/23 can offer an option of treating both IBD and associated inflammatory arthritis. JAKi DMARDs may be considered for selected enteropathic arthritis cases, though there is variation among the group of JAKi drugs with regard to their efficacy (and licensing) for treating both ulcerative colitis and Crohn disease.

Autoimmune connective tissue diseases

Autoimmune connective tissue diseases (CTD) share many clinical features and are characterised by dysregulation of immune responses and tissue damage, with autoantibody production that is often directed at components of the cell nucleus.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a rare disease with a prevalence that ranges from about 0.03% in people of European descent to 0.2% in people of African Caribbean origin. Some 90% of affected patients are female and the peak age at onset is between 20 and 30 years. SLE is associated with considerable morbidity and a fivefold increase in mortality compared to age- and gender-matched controls, mainly because of an increased risk of premature cardiovascular disease.

Pathophysiology

The cause of SLE is incompletely understood. Genetic factors play a role, and the strongest region of association lies with alleles in the HLA-DR and DQ regions. However, many other susceptibility loci, which lie within or close to genes involved in the immune response, have also been identified by genome-wide association studies. The overall heritability of SLE has been estimated to be about 40%–60%, illustrating that environmental influences play a role in triggering the disease, but it is not clear what these are. In a few instances, SLE can have a monogenic basis due to loss-of-function pathogenic variants in complement components C1q, C2 and C4, and common polymorphic variants in the immunoglobulin receptor FcγRIIIb. From an immunological standpoint, the characteristic feature of SLE is autoantibody production. These autoantibodies have specificity for a wide range of targets, but many are directed against antigens present within the cell or within the nucleus. This has led to the hypothesis that SLE may occur because of defects in apoptosis or in the clearance of apoptotic cells, which causes inappropriate exposure of intracellular antigens on the cell surface, leading to polyclonal B- and T-cell activation, and autoantibody production. In support of this, environmental factors that cause flares of SLE, such as ultraviolet light and infections, increase oxidative stress and cause cell damage. Whatever the underlying cause, autoantibody production and immune complex formation are thought to be important mechanisms of tissue damage in SLE, leading to vasculitis and organ damage.

Clinical features

Symptoms such as fever, weight loss and lymphadenopathy may occur during flares of disease activity, whereas others such as fatigue and polyarthralgia are frequent and in many patients are not associated with active inflammatory disease.

Arthritis

Arthralgia is a common symptom, occurring in 90% of patients, and is often associated with early morning stiffness. Tenosynovitis may also occur, but clinically apparent synovitis with joint swelling is unusual. Joint deformities may arise (Jaccoud arthropathy) as the result of tendon damage, but joint erosions are not a feature.

Raynaud phenomenon

Raynaud phenomenon (RP) is characterised by vasoconstriction of the small vessels of the hands and feet in response to cold, leading to pallor followed by cyanosis of the affected digits followed by vasodilatation causing the affected digits to turn red. This is a common feature of SLE and may antedate other symptoms by months or years. Raynaud phenomenon associated with SLE and other CTD (secondary RP) needs to be differentiated from primary RP, which is a benign disorder that is common in the general population (up to 5%). Features of secondary RP include age at onset of over 25 years, other features of CTD, absence of a family history of RP, severity of symptoms, presence of digital ulceration (Fig. 25.43) and male gender. Examination of capillary nail-fold loops using an ophthalmoscope (with oil placed on the skin) can show loss of the normal loop pattern, with capillary 'fallout' and dilatation and branching of loops; these features support a diagnosis of secondary RP but can be observed in severe primary RP.

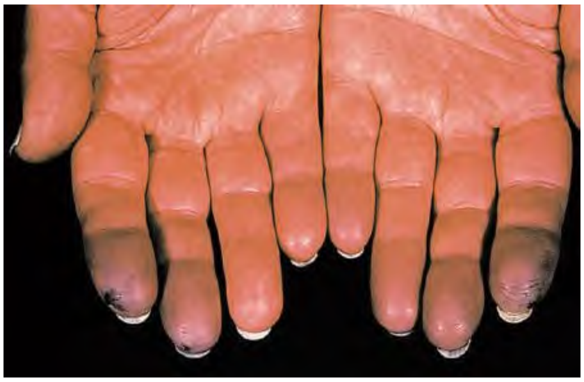

Fig. 25.43 Severe secondary Raynaud phenomenon leading to ischaemic digital ulceration.

Skin

The skin is commonly involved in SLE, and many eruptions are precipitated by exposure to ultraviolet light. The main types of skin involvement are:

- The classic malar facial rash (up to 20% of patients). This is erythematous, raised and painful or itchy, and occurs over the cheeks with sparing of the nasolabial folds (Fig. 25.44). Rosacea may mimic this rash.
- A discoid rash characterised by hyperkeratosis and follicular plugging, with scarring alopecia if it occurs on the scalp.
- Diffuse, usually non-scarring alopecia, which may also occur with active disease.
- Urticarial eruptions.
- Livedo reticularis (Fig. 25.45), which is also a feature of antiphospholipid syndrome and can become frankly vasculitic, if severe.

Kidney

Renal involvement is one of the main determinants of prognosis and regular monitoring of urinalysis and blood pressure is essential. The typical

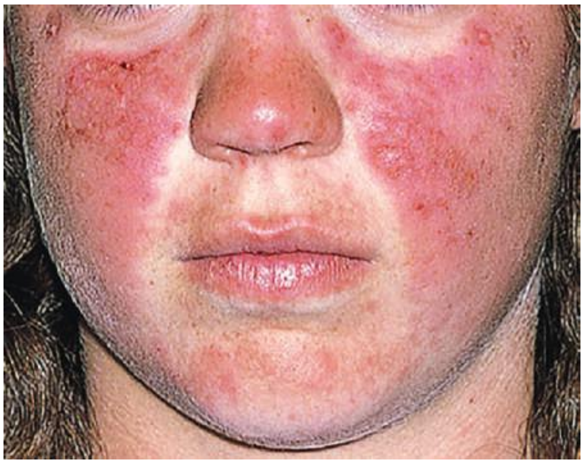

Fig. 25.44 Malar rash of systemic lupus erythematosus, sparing the nasolabial folds. The rash, when mild, can be notably similar to rosacea, which may itself be associated with inflammatory joint diseases that are associated with enteral diseases.

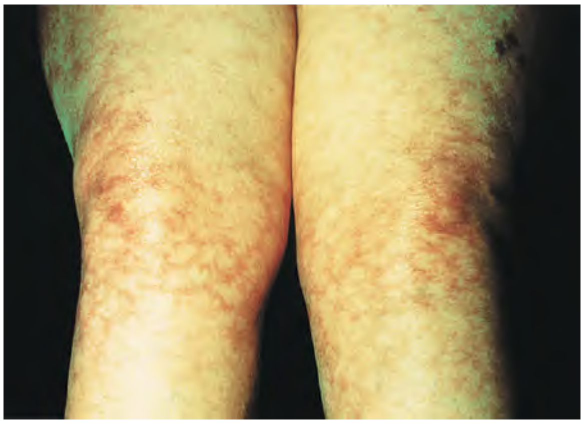

Fig. 25.45 Livedo reticularis (as typically occurs in systemic lupus erythematosus and antiphospholipid syndrome).

renal lesion is a proliferative glomerulonephritis, characterised by haematuria, proteinuria and casts on urine microscopy.

Cardiovascular

The most common manifestation is pericarditis. Myocarditis and Libman–Sacks endocarditis can also occur. The endocarditis is due to accumulation on the heart valves of sterile fibrin-containing vegetations, which is thought to be a manifestation of hypercoagulability associated with antiphospholipid antibodies. The risk of atherosclerosis is greatly increased, as is the risk of stroke and myocardial infarction. This is thought to be multifactorial due to the adverse effects of inflammation on the endothelium, chronic glucocorticoid therapy and the procoagulant effects of antiphospholipid antibodies.

Lung

Lung involvement is common and most frequently manifests as pleuritic pain (serositis) or pleural effusion. Other features include pneumonitis, atelectasis, reduced lung volume and pulmonary fibrosis. The risk of thromboembolism is increased, especially in patients with antiphospholipid antibodies.

Neurological

Fatigue, headache and poor concentration are common and often occur in the absence of laboratory evidence of active disease. More specific features of cerebral SLE include visual hallucinations, chorea, organic psychosis, transverse myelitis and lymphocytic meningitis.

Haematological

Neutropenia, lymphopenia, thrombocytopenia and haemolytic anaemia may occur, due to antibody-mediated destruction of peripheral blood cells. The degree of lymphopenia can sometimes be a guide to disease activity.

Gastrointestinal

Mouth ulcers may occur and can be painful. Peritoneal serositis can cause acute pain. Mesenteric vasculitis is a serious complication, which can present with abdominal pain, bowel infarction or perforation. Hepatitis is a recognised, though rare, feature.

Paediatric disease

Renal disease and cutaneous manifestations are more frequent in juvenile-onset SLE compared to disease in adults. Similarly, there is subsequently a higher incidence of renal disease, malar rash, Raynaud phenomenon, cutaneous vasculitis and neuropsychiatric manifestations than in adults.

Investigations

The diagnosis is based on a combination of clinical features and laboratory abnormalities. To fulfil the classification criteria for SLE, at least 4 of the 11 factors shown in Box 25.62 must be present or have occurred in the past. Checking of ANA, antibodies to ENA and complement, routine haematology, biochemistry and urinalysis are mandatory. Patients with active SLE are almost always positive for ANA. While ANA-negative SLE can occur, this is rare and in such cases antibodies to Ro or antiphospholipid antibodies are usually present. Anti-dsDNA antibodies are positive in most patients and are quite specific for SLE. Serum levels of C3 may be low in active SLE due to complement consumption, but in some people low C3 and C4 can also be caused by inherited deficiencies in C1, C2 or C4, all of which predispose to SLE. Studies of other family members can help to differentiate inherited deficiencies from complement consumption. A raised ESR, leucopenia and lymphopenia are typical of active SLE, and this may be accompanied by anaemia, haemolytic anaemia and thrombocytopenia. The CRP may be normal or only slightly raised in active SLE. A significantly elevated CRP raises the possibility of either serositis, or coexisting infection.

Management

The therapeutic goals are to educate the patient about the nature of the illness, to control symptoms and to prevent organ damage and maintain normal function. Patients should be advised to avoid sun and ultraviolet light exposure and to employ sun blocks (sun protection factor 50). Management of RP is as described in the section on systemic sclerosis below.

i 25.62 Criteria for the classification of systemic lupus erythematosus

Features	Characteristics
Malar rash	Fixed erythema, flat or raised, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scarring and follicular plugging
Photosensitivity	Rash due to unusual reaction to sunlight
Oral ulcers	Oral or nasopharyngeal ulceration, which may be painless
Arthritis	Non-erosive, involving two or more peripheral joints
Serositis	Pleuritis (history of pleuritic pain or rub, or pleural effusion) *or* pericarditis (rub, electrocardiogram evidence or effusion)
Renal disorder	Persistent proteinuria > 0.5 g/24 hrs *or* cellular casts (red cell, granular or tubular)
Neurological disorder	Seizures or psychosis, in the absence of provoking drugs or metabolic derangement
Haematological disorder	Haemolytic anaemia *or* leucopenia* ($< 4 \times 10^9$/L) *or* lymphopenia* ($< 1 \times 10^9$/L) *or* thrombocytopenia* ($< 100 \times 10^9$/L) in the absence of offending drugs
Immunological	Anti-DNA antibodies in abnormal titre *or* presence of antibody to Sm antigen *or* positive antiphospholipid antibodies
Antinuclear antibody (ANA)	Abnormal titre of ANA by immunofluorescence

An adult has SLE if any 4 of 11 features are present serially or simultaneously

*On two separate occasions.

Mild to moderate disease

Patients with mild disease restricted to skin and joints can sometimes be managed with analgesics, NSAIDs and HCQ. Immunosuppressants such as MTX, azathioprine or MMF are generally required in patients with moderate disease along with glucocorticoids (prednisolone 5–20 mg/day). The maintenance dose of prednisolone should be kept as low as possible, but increased doses may be required for flares in activity or complications such as pleurisy or pericarditis. These medicines often do not help fatigue, which is frequently problematic. This may respond to low intensity regular aerobic exercise. Poor sleep hygiene should be addressed to try to combat this symptom.

Severe and life-threatening disease

High-dose glucocorticoids and immunosuppressants are required for the treatment of renal, CNS and cardiac involvement. A commonly used regimen is pulsed methylprednisolone (500–1000 mg IV) on three occasions plus cyclophosphamide (15 mg/kg IV), repeated at 2- to 3-weekly intervals for six to eight cycles accompanied by MESNA to prevent haemorrhagic cystitis. Because of the risk of azoospermia and premature menopause, sperm or oocyte collection and storage may need to be considered prior to treatment with cyclophosphamide.

High-dose glucocorticoids have been successfully combined with MMF with results similar to those of pulsed cyclophosphamide, but with fewer adverse effects. Belimumab in combination with standard therapy significantly decreases disease activity in SLE patients and is safe and well tolerated. Its role in patients with renal and neurological disease is still under investigation. Rituximab has been reported as being effective in case reports and case series, but randomised placebo-controlled trials have not shown benefit or a steroid-sparing effect in moderate to severe SLE.

Maintenance therapy

Following induction therapy, oral prednisolone should be commenced in a dose of 40–60 mg daily, gradually reducing to between 5 and 10 mg/day by 3 months. Immunosuppressive therapy with azathioprine, MTX or MMF should be prescribed to maintain remission with the lowest maintenance dose of glucocorticoid possible. Cardiovascular risk factors, such as obesity, hypertension and hyperlipidaemia, should be controlled and patients should be advised to stop smoking and avoid excess alcohol intake.

Patients with SLE positive for antiphospholipid antibodies, without previous episodes of thrombosis, should be given prophylaxis with low-dose aspirin. Those with previous episodes of thrombosis require life-long anticoagulant therapy with either warfarin or direct acting anticoagulants such as apixiban. Patients with SLE are at risk of osteoporosis, and DXA should be considered in those who require prednisolone in a dose of > 7.5 mg/day for more than 3 months or those with a 10-year fracture risk of >10%.

Systemic sclerosis

Systemic sclerosis (SSc) is an autoimmune disorder of connective tissue, which results in fibrosis affecting the skin, internal organs and vasculature. It is characterised by severe Raynaud phenomenon, sometimes complicated by digital ischaemia (see Fig. 25.43), sclerodactyly, cardiac, lung, gut and renal disease. The peak age of onset is in the fourth and fifth decades. It is a rare condition with a prevalence of 10–20 per 100 000, with a 4:1 female-to-male ratio. It is generally subdivided into limited cutaneous systemic sclerosis (lcSSc; 70% of cases) and diffuse cutaneous systemic sclerosis (dcSSc; 30% of cases) depending on the extent of skin involvement. Some patients with lcSSc have calcinosis and telangiectasia, and when combined with Raynaud phenomenon, oesophageal involvement and sclerodactyly this is referred to as the CREST syndrome (*C*alcinosis, *R*aynaud, o*E*sophageal involvement, *S*clerodactyly and *T*elangiectasia). The prognosis in lcSSc is good, with a 10-year survival of 92%. The prognosis of dcSSc is less favourable (overall 10-year survival 65%) and is worst in those with pulmonary arterial hypertension or interstitial lung disease.

Pathophysiology

The cause of SSc is not completely understood. There is evidence for a genetic component, and associations with alleles at the HLA locus have been found. The disease occurs in all ethnic groups, and race may influence severity. Isolated cases have been reported in which an SSc-like disease has been triggered by exposure to silica dust, vinyl chloride, epoxy resins and trichloroethylene. There is clear evidence of immunological dysfunction: T lymphocytes, especially those of the Th17 subtype, infiltrate the skin and there is abnormal fibroblast activation, leading to increased production of extracellular matrix in the dermis, primarily type I collagen. This results in symmetrical thickening, tightening and induration of the skin (scleroderma). Arterial and arteriolar narrowing occurs due to intimal proliferation and vessel wall inflammation. Endothelial injury causes release of vasoconstrictors and platelet activation, resulting in further ischaemia, which is thought to exacerbate the fibrotic process.

Clinical features

Skin

Initially, there is non-pitting oedema of fingers and flexor tendon sheaths. Subsequently, the skin becomes shiny and taut, and distal skin creases disappear. There can be capillary loss. The face and neck are often involved, with thinning of the lips and radial furrowing. In some patients, skin thickening stops at this stage. Skin involvement restricted to sites distal to the elbow or knee (apart from the face) is classified as lcSSc (Fig. 25.46). Telangiectasia, typically affecting the face, is a feature of lcSSc (Fig. 25.47). Involvement proximal to the knee and elbow and on the trunk is classified as dcSSc.

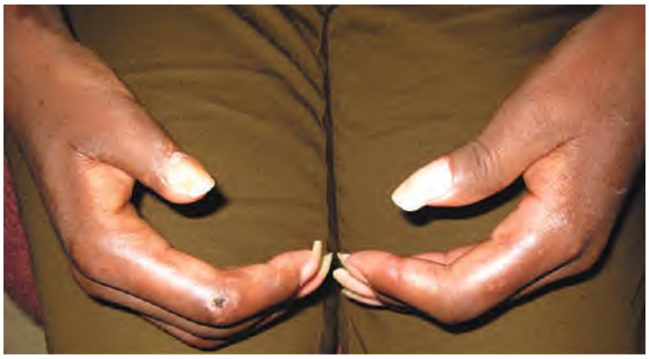

Fig. 25.46 Systemic sclerosis. Hands showing tight, shiny skin, sclerodactyly and flexion contractures of the fingers. *From Callen J, Jorizzo J, Zone J, Piette W, Rosenbach M, Vleugels RA. Dermatological signs of systemic disease. 5th ed. Elsevier; 2017.*

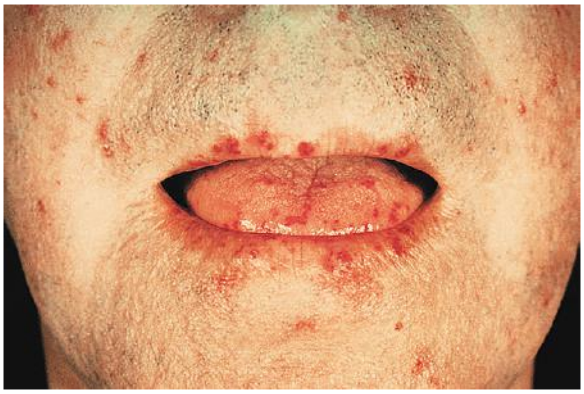

Fig. 25.47 Typical facial appearance showing telangiectasias in localised cutaneous systemic sclerosis.

Raynaud phenomenon

This is a universal feature and can precede other features by many years. Involvement of small blood vessels in the extremities may cause critical tissue ischaemia, leading to localised distal skin infarction and necrosis.

Musculoskeletal features

Arthralgia and flexor tenosynovitis are common. Restricted hand function is due to skin involvement rather than joint disease and erosive arthropathy is uncommon. Muscle weakness and wasting can result from myositis.

Gastrointestinal involvement

Involvement of the GI tract is almost universal in SSc. Oesophageal dysmotility and symptoms of gastro-oesophageal reflux are very common and may be associated with heartburn, causing dysphagia and odynophagia. Involvement of the stomach can cause delayed gastric emptying (gastroparesis) causing early satiety, postprandial fullness, bloating, distention, abdominal pain, nausea and vomiting. Gastric antral vascular ectasia (GAVE) is caused by arteriovenous malformations in the mucosa of the gastric antrum. It is relatively rare (1%) but can present with GI bleeding or iron deficiency anaemia. Small intestine dysmotility can lead to stasis of intestinal contents and dilation, also known as pseudo-obstruction, which presents with nausea, vomiting, abdominal discomfort and distension and constipation. Malabsorption can occur due to bacterial overgrowth.

Pulmonary involvement

Pulmonary hypertension may complicate long-standing disease and is six times more prevalent in dcSSc than in lcSSc. It usually presents with insidiously evolving exertional dyspnoea and signs of right heart failure. Interstitial lung disease is common in patients with dcSSc and is associated with the presence of topoisomerase 1 antibodies (Scl70). Dyspnoea can evolve slowly over time or progress rapidly in some cases.

Renal involvement

One of the main causes of death is hypertensive renal crisis, characterised by rapidly developing accelerated phase hypertension and renal failure. Hypertensive renal crisis is much more likely to occur in dcSSc than in lcSSc and is associated with the presence of anti-Scl70 and anti-RNP antibodies.

Investigations

As SSc can affect multiple organs, routine haematology, renal, liver and bone function tests and urinalysis are essential. Screening for antinuclear antibodies and extractable nuclear antibodies should be performed. The ANA is positive in about 95%, and about 30% of patients with dcSSc have antibodies to topoisomerase 1 (Scl70). About 60% of patients have anticentromere antibodies. This is a biomarker for CREST syndrome. Chest X-ray, transthoracic echocardiography and lung function tests are recommended to screen for the presence of interstitial lung disease and pulmonary hypertension. High-resolution lung CT is recommended if any of these investigations yield abnormal results. Upper GI endoscopy, barium swallow and esophageal manometry can be used to assess oesophageal involvement. A hydrogen breath test can indicate small intestinal bacterial overgrowth.

Management

The focus of management is to ameliorate symptoms and combat the effects of the disease on target organs. There is evidence that patients with severe dcSSc with a poor prognosis may benefit from high-intensity immunosuppression (usually including cyclophosphamide) followed by autologous haematopoietic stem cell transplantation (HSCT). The potential risks of this strategy are considerable, however, due to increased mortality as an adverse effect of the treatment.

- *Skin fibrosis*. There is evidence that MMF can improve skin fibrosis in SSc, and this should be considered in all patients with dcSSc. Alternative immunosuppressives that can be tried include MTX and rituximab.
- *Raynaud phenomenon and digital ulcers*. Avoidance of cold exposure, use of thermal insulating gloves/socks and maintenance of a high core temperature can all help prevent attacks of RP. Calcium channel blockers are first-line drug treatment, followed by PDE5 inhibitors such as tadalafil if adverse effects occur or the response is inadequate. Courses of intravenous epoprostenol can be used for severe RP with digital ischaemia. The endothelin-1 antagonist bosentan is licensed for treating ischaemic digital ulcers, and digital tip tissue health can be maintained with regular use of fucidin–hydrocortisone cream.
- *Gastrointestinal complications*. Oesophageal reflux can be treated with proton pump inhibitors and anti-reflux agents. Rotating courses of antibiotics may be required for small intestinal bacterial overgrowth (p. 867), while prokinetic agents such as metoclopramide or domperidone may help patients with symptoms of dysmotility/pseudo-obstruction.
- *Hypertension*. Treatment with ACE inhibitors is needed, even if renal impairment is present.
- *Joint involvement*. This may be treated with analgesics and/or NSAIDs. If synovitis is present, therapy with MTX or another csDMARD can be of value.
- *Pulmonary hypertension*. The endothelin-1 antagonist ambrisentan 10 mg daily combined with tadalafil 40 mg daily are first-line treatments for pulmonary arterial hypertension. The soluble guanylate cyclase agonist riociguat in a dose of 1.5–2.5 mg daily is another option. In progressive disease, heart–lung transplant may be considered.
- *Interstitial lung disease*. Cyclophosphamide is effective in slowing progression of interstitial lung disease (ILD), and similar results have been observed with MMF. The tyrosine kinase inhibitor nintedanib (150 mg twice daily) has also shown efficacy in the treatment of ILD associated with SSc and is licensed for this indication. Other options include rituximab and the IL-6 inhibitor tocilizumab, both of which have been found to be effective in SSc-ILD. Tocilizumab has recently been approved by the FDA for SSc-ILD.

Sjögren disease

Sjögren disease (SD) is characterised by dryness and grittiness of the eyes and dryness of the mouth due to lymphocytic infiltration of salivary and lacrimal glands, leading to glandular fibrosis and exocrine failure. The typical age of onset is between 40 and 50 years, with a 9:1 female-to-male ratio. It is subdivided into primary Sjögren disease (PSD), which occurs in the absence of other autoimmune disease, and secondary Sjögren disease, where it occurs in association with other conditions like RA, SLE and other CTDs.

Clinical features

The eye symptoms, termed keratoconjunctivitis sicca, are due to a lack of lubricating tears, which reflects inflammatory infiltration of the lacrimal glands. Conjunctivitis and blepharitis are frequent and may lead to filamentary keratitis due to binding of tenacious mucous filaments to the cornea and conjunctiva. Oral involvement manifests as a dry mouth (xerostomia). There is a high incidence of dental caries, gingivitis, periodontitis and other dental problems. Lymphadenopathy is present in about two-thirds of patients and other sites of extraglandular involvement are listed in Box 25.63. Often the most disabling symptom is fatigue. There may be an association with inflammatory small-joint OA, although formal studies have not been done to determine if this is a chance association. Sialadenitis, osteoarthritis and xerostomia (SOX) syndrome has been described; this may occur independently of PSD or, more likely, constitutes a mild form. Both interstitial lung disease (presenting with dry cough, dyspnoea and course crackles on lung auscultation) and interstitial nephritis (presenting with polyuria and sometimes complicated by renal tubular acidosis) may occur and both require proactive screening. PSD is associated with a 40-fold increased lifetime risk of lymphoma,

25.63 Features of primary Sjögren disease

Risk factors

- Age of onset 40–60
- Female > male
- HLA-B8/DR3

Common clinical features

- Keratoconjunctivitis sicca
- Xerostomia
- Salivary gland enlargement
- Rashes/skin irritation
- Non-erosive arthralgia
- Generalised osteoarthritis
- Raynaud phenomenon
- Fatigue

Less common features

- Low-grade fever
- Interstitial lung disease
- Anaemia, leucopenia
- Thrombocytopenia
- Cryoglobulinaemia
- Vasculitis
- Peripheral neuropathy
- Lymphadenopathy
- Lymphoreticular lymphoma
- Glomerulonephritis
- Interstitial nephritis
- Renal tubular acidosis

Autoantibodies frequently detected

- Rheumatoid factor
- Antinuclear antibody
- SS-A (anti-Ro)
- SS-B (anti-La)
- Gastric parietal cell
- Thyroid

Associated autoimmune disorders

- Systemic lupus erythematosus
- Systemic sclerosis
- Coeliac disease
- Primary biliary cholangitis
- Chronic active hepatitis
- Myasthenia gravis

(HLA = human leucocyte antigen)

though the complication is still very rare. This should be suspected if there is progressive worsening of lymphadenopathy.

Investigations

Support for the diagnosis can be obtained by the Schirmer tear test, which measures tear flow over 5 minutes using absorbent paper strips placed on the lower eyelid; a normal result is more than 5 mm of wetting. Corneal staining with rose bengal may show punctate epithelial abnormalities over the area not covered by the open eyelid. If the diagnosis remains in doubt, it can be confirmed by demonstrating focal lymphocytic infiltrate in a minor salivary gland biopsy. Most patients have an elevated ESR and hypergammaglobulinaemia, and one or more autoantibodies, including anti-Ro (up to 75%) and anti-La (up to 50%). About 80% of patients test positive for ANA and 65% for RF but anti-CCP antibodies are less common (10%). ANA-negative disease does exist, but in this case anti-Ro and anti-La antibodies are usually detectable (see Box 25.9). A chest X-ray, high resolution CT and lung function tests should be performed if symptoms suggestive of lung disease are present. Routine biochemistry and tests of urinary concentrating ability may be required if interstitial nephritis is suspected. Lymph node biopsy should be performed to exclude lymphoma in patients with progressive lymphadenopathy.

Management

No treatments can significantly modify the course of PSD and so management is essentially symptomatic. Lacrimal substitutes, such as hypromellose, should be used during the day in combination with more viscous lubricating application at night. Soft contact lenses can be useful for corneal protection in patients with filamentary keratitis, and occlusion of the lacrimal ducts is occasionally needed. Artificial saliva sprays, saliva-stimulating tablets, pastilles and oral gels can be tried for xerostomia, but often chewing gum is most effective. Adequate post-prandial oral hygiene and prompt treatment of oral candidiasis are essential. Vaginal dryness is treated with lubricants. A trial of systemic pilocarpine (5–30 mg daily in divided doses) is worthwhile in early disease to increase salivary and lacrimal secretions. HCQ is sometimes used in the treatment of SS, but clinical trials have not shown convincing evidence of benefit. Immunosuppression does not improve sicca symptoms. Patients with ILD should be treated along the same lines as described for SSc-ILD. Immunosuppressives are often used in the treatment of interstitial nephritis but the evidence base for benefit is limited.

Polymyositis and dermatomyositis

Polymyositis (PM) and dermatomyositis (DM) are characterised by an inflammatory infiltrate of both skeletal and smooth muscle. In DM, characteristic skin changes also occur. Both diseases are rare, with an incidence of 2–10 cases per million/year. They can occur in isolation or in association with other autoimmune diseases and both may be the presenting features of a previously undiagnosed malignancy.

Clinical features

The typical presentation of PM and DM is with symmetrical proximal muscle weakness over a few weeks, usually affecting the lower limbs more than the upper, in adults between 40 and 60 years of age. Patients report difficulty rising from a chair, climbing stairs and lifting. Muscle pain is not a prominent feature but may be present in up to one-third of patients. Systemic features of fever, weight loss and fatigue are common. Subcutaneous calcification associated with skin ulceration may occur in both DM and PM. Respiratory or pharyngeal muscle involvement can lead to ventilatory failure or aspiration that requires urgent treatment. Interstitial lung disease occurs in up to 30% of patients and is associated with the presence of antisynthetase (Jo-1) antibodies.

The skin lesions in DM include Gottron papules, which are scaly, erythematous or violaceous, psoriasiform plaques occurring over the extensor surfaces of PIP and DIP joints, and a heliotrope rash that is a violaceous discoloration of the eyelid in combination with periorbital oedema (Fig. 25.48). Similar rashes occur on the upper back, chest and shoulders over a 'shawl' distribution. Periungual nail-fold capillaries are often enlarged and tortuous.

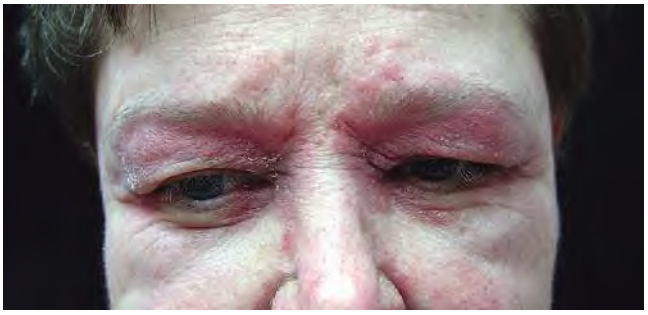

Fig. 25.48 Heliotrope rash and eyelid oedema in dermatomyositis. *From Callen JP, Jorizzo JL, Bolognia JL, Piette WW, Zone JZ. Dermatological signs of internal disease. 4th ed. Elsevier; 2009.*

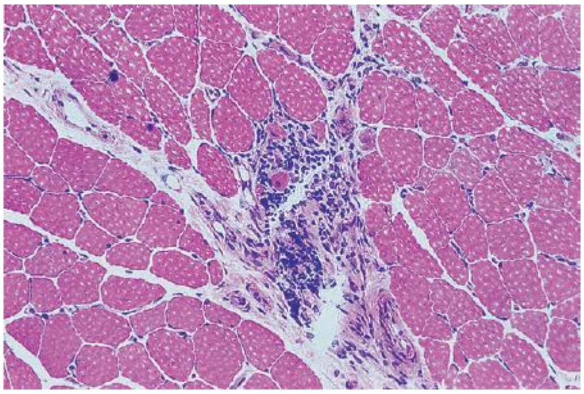

Fig. 25.49 Muscle biopsy from a patient with polymyositis. The sample shows an intense inflammatory cell infiltrate in an area of degenerating and regenerating muscle fibres.

Investigations

Muscle biopsy is the pivotal investigation and shows the typical features of fibre necrosis, regeneration and inflammatory cell infiltrate (Fig. 25.49). Since muscle involvement may be patchy, it is common to perform an MRI scan prior to biopsy, which often shows features of increased signal intensity in STIR sequence images, consistent with inflammatory change. This not only provides support for the diagnosis, but also can help choose the optimal site for a biopsy. Serum levels of CK are typically raised and are a useful measure of disease activity, but a normal CK does not exclude the diagnosis, particularly in juvenile DM and PM. Electromyography can be useful in differentiating DM and PM from non-inflammatory myopathies. Screening for underlying malignancy should be undertaken routinely (full examination, chest X-ray, serum urine and protein electrophoresis, CT of chest/abdomen/pelvis; prostate-specific antigen in men and mammography in women).

Management

Oral prednisolone 60–80 mg daily is the first-line treatment of PM and DM, but high-dose intravenous methylprednisolone (1 g/day for 3 days) may be required in patients with respiratory or pharyngeal weakness. If there is a good response, glucocorticoids should be reduced by approximately 25% per month, aiming for a maintenance dose of 5–7.5 mg daily. Glucocorticoid-induced myopathy should be considered in patients who initially respond but then relapse. A second muscle biopsy can be of diagnostic value to guide further treatment in this situation since, in the case of glucocorticoid myopathy type II, fibre atrophy is observed as compared with fibre necrosis and regeneration in active myositis. Treatment should be adjusted accordingly. Although most patients respond well to glucocorticoids, additional immunosuppressive therapy is usually required as steroid-sparing agents in the form of MTX, azathioprine, MMF or ciclosporin. Rituximab is sometimes used in refractory cases, but the only randomised trial of this agent did not show benefit over placebo. Intravenous immunoglobulin (IVIg) has been shown to be effective in the treatment of DM and is often used in the treatment of refractory PM and DM. Antimalarials such as HCQ and mepacrine have been used for skin-predominant disease, but the evidence for benefit is limited and based on case reports.

Juvenile dermatomyositis

Juvenile dermatomyositis (JDM) is by far the most common inflammatory myopathy in children and adolescents; it does not require a search for underlying malignancy. The incidence is 2–4 per million (United States and UK), with a median age of onset of 7 years (25% are below 4 years at diagnosis). Many clinical features are like those in adult disease. JDM can be monocyclic, lasting up to 3 years (25%–40%), or polycyclic with periods of remission and relapse (60%–75%). In some cases, polycyclic JDM can be chronic and life-long. Skin ulceration occurs in 10%–20% of cases and calcinosis in about 30%. Intravenous methylprednisolone then oral glucocorticoids and MTX produce a rapid response in many cases. Cyclophosphamide may be used for resistant disease with skin ulceration. IVIg is given in resistant cases.

Inclusion body myositis

Inclusion body myositis (IBM) is the most frequent primary myopathy in middle age and after. It is characterised by slowly progressive muscle weakness and atrophy, with pathological changes of inflammation, degeneration and mitochondrial abnormality in affected muscle fibres. IBM typically presents with distal muscle weakness. In time, muscles atrophy. Investigation is the same as for polymyositis. There is typically slightly elevated CK and myopathic changes on EMG. Muscle biopsy shows abnormal fibres containing rimmed vacuoles and filamentous inclusions in the nucleus and cytoplasm. Therapeutic response to glucocorticoids and immunosuppressants is poor. There is anecdotal report of efficacy with IVIg, but trial evidence is lacking.

Mixed connective tissue disease

Mixed connective tissue disease (MCTD) is a condition in which some clinical features of SSc, myositis, SLE, and rheumatoid arthritis occur in the same patient. It commonly presents with indolent puffiness of the fingers, Raynaud phenomenon, muscle pain, weakness and synovitis. Anti-RNP antibodies are a biomarker for this diagnosis in combination with high titres of ANA. Other autoantibodies are typically negative. Management focuses on treating the individual components of the disease (see other sections).

Undifferentiated autoimmune connective tissue disease

Undifferentiated autoimmune connective tissue disease is used to describe the situation where patients present with individual clinical features of CTD, either simultaneously or sequentially, but do not meet the criteria for diagnosis of a specific disease. Some may progress to develop a specific CTD with time; others continue to have an undifferentiated disease that remains the same for many years, and in others the symptoms will recede. These patients should be kept under review with management directed at treating individual symptoms as they arise.

Adult-onset Still disease

Adult-onset Still disease is a rare systemic inflammatory disorder of unknown cause with features similar to sJIA and familial fever syndromes (p. 74). The presentation is with intermittent fever, rash and polyarthritis or polyarthralgia. There is evidence that increased production of the pro-inflammatory cytokine interleukin-1 may play a pathogenic role. Splenomegaly, hepatomegaly and lymphadenopathy may be present. Investigations typically provide evidence of an acute phase response with raised ESR and CRP and a markedly elevated serum ferritin. Tests for RF and ANA are negative. Treatment with NSAIDs can be effective in mild cases, but in more severe disease, glucocorticoids with or without csDMARDs such as azathioprine, MTX or MMF are indicated. In resistant disease, the interleukin-1 inhibitors canakinumab or anakinra can be highly effective.

Vasculitis

Vasculitis is characterised by inflammation and necrosis of blood vessel walls, with associated damage to skin, kidney, lung, heart, brain and gastrointestinal tract. There is a wide spectrum of involvement and severity, ranging from mild and transient disease affecting only the skin, to life-threatening fulminant disease with multiple organ failure. Principal sites of involvement for the main types of vasculitis are summarised in Figure 25.50. The clinical features result from a combination of local tissue ischaemia (due to vessel inflammation and narrowing) and the systemic effects of widespread inflammation. Systemic vasculitis should be considered in any patient with fever, weight loss, fatigue, evidence of multisystem involvement, rashes, raised inflammatory markers and abnormal urinalysis (Box 25.64).

Antineutrophil cytoplasm antibody-associated vasculitis

Antineutrophil cytoplasm antibody (ANCA)-associated vasculitis (AAV) is a life-threatening disorder characterised by inflammatory infiltration of small blood vessels, fibrinoid necrosis and the presence of circulating antibodies to antineutrophil cytoplasm antibody (ANCA). The combined incidence is about 10–15/1 000 000. There are three main subtypes with differing clinical features:

Microscopic polyangiitis

Microscopic polyangiitis (MPA) is a necrotising small-vessel vasculitis found with rapidly progressive glomerulonephritis, often in association with alveolar haemorrhage. Cutaneous (Fig. 25.51B) and gastrointestinal involvement are common, and other features include neuropathy (15%) and pleural effusions (15%). Patients are usually myeloperoxidase (MPO) antibody-positive.

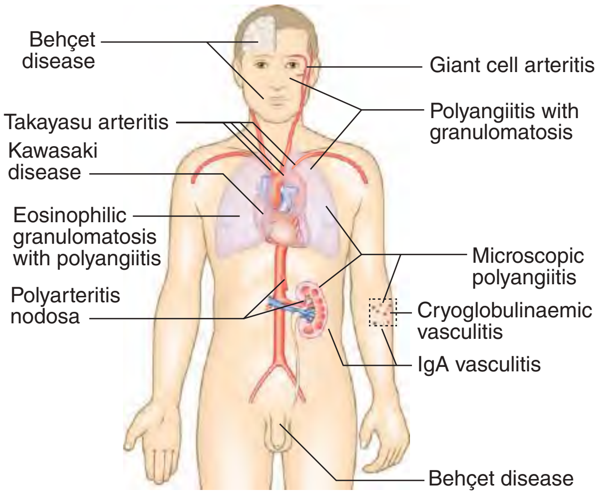

Fig. 25.50 **Types of vasculitis.** The anatomical targets of different forms of vasculitis are shown.

i 25.64 Clinical features of systemic vasculitis

Systemic	
• Malaise • Fever • Night sweats	• Weight loss • Myoarthralgias
Rashes	
• Palpable purpura • Pulp infarcts	• Ulceration • Livedo reticularis
Ear, nose and throat	
• Epistaxis • Recurrent sinusitis	• Deafness
Respiratory	
• Haemoptysis • Cough	• Poorly controlled asthma
Gastrointestinal	
• Abdominal pain (due to mucosal inflammation or enteric ischaemia) • Diarrhoea	• Mouth ulcers
Neurological	
• Sensory or motor neuropathy	

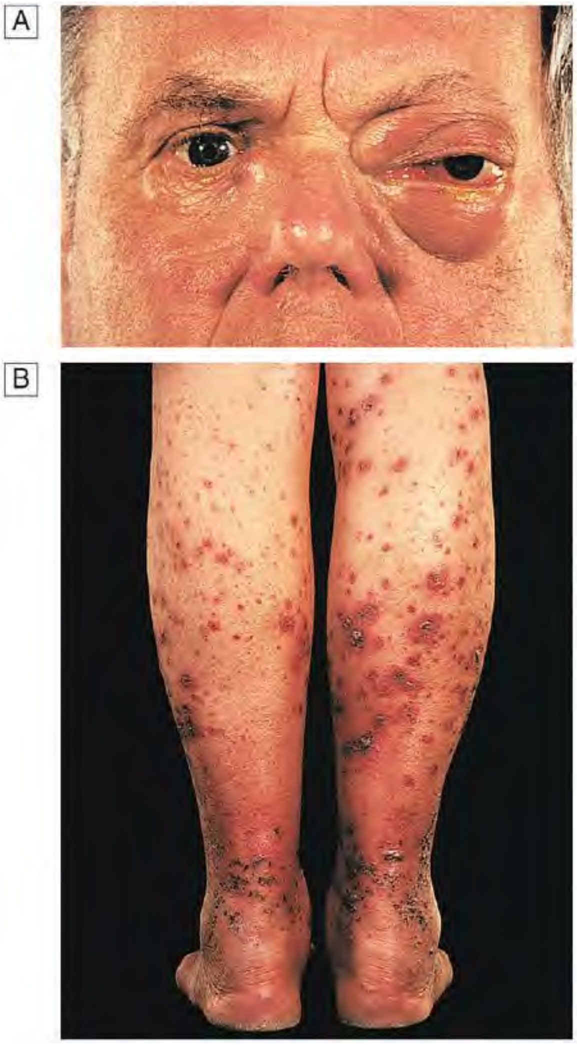

Fig. 25.51 A Proptosis secondary to ocular involvement in GPA. B Purpuric skin rash in MPA.

Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (GPA) is characterised by granuloma formation, mainly affecting the nasal passages, airways and kidney. Fewer patients with GPA present with glomerulonephritis than with MPA. The most common presentation of GPA is with epistaxis, nasal crusting and sinusitis, but haemoptysis and mucosal ulceration may also occur. Deafness may be a feature due to inner ear involvement and proptosis may occur because of inflammation of the retro-orbital tissue (see Fig. 25.51A). This causes diplopia due to entrapment of the extra-ocular muscles, or loss of vision due to optic nerve compression. Disturbance of colour vision is an early feature of optic nerve compression. Untreated nasal disease ultimately leads to destruction of bone and cartilage. Migratory pulmonary infiltrates and nodules occur in 50% of patients (as seen on high-resolution CT of lungs). Patients with GPA are usually proteinase-3 (PR3) antibody-positive.

Eosinophilic granulomatosis with polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA, formerly known as Churg–Strauss syndrome) is a small-vessel vasculitis with an incidence of about 1–3 per 1 000 000. Antibodies to MPO or PR3 can be detected in up to 60% of cases. It is somewhat distinct from MPA and GPA in that eosinophilia is a prominent feature. Some patients have a prodromal period for many years, characterised by allergic rhinitis, nasal polyposis and late-onset asthma that is often difficult to control. The typical acute presentation is with a triad of skin lesions (purpura or nodules), asymmetric mononeuritis multiplex and eosinophilia. Pulmonary infiltrates and pleural or pericardial effusions due to serositis may be present. Up to 50% of patients have abdominal symptoms provoked by mesenteric vasculitis.

Investigation of AAV

Patients with active disease usually have leucocytosis with elevated CRP and ESR. Complement levels are usually normal or slightly elevated. Eosinophilia is suggestive of EGPA. Imaging of the upper airways, chest and nasal passages with MRI can be useful in localising abnormalities in GPA. Often, the diagnosis of AAV can be made on clinical and serological grounds in combination with the laboratory abnormalities described above, but if there is any doubt, biopsy of the kidney, skin or lesions in the sinuses and upper airways should be performed.

Management

Initial management of AAV is with immunosuppressive therapy with either cyclophosphamide or rituximab coupled with glucocorticoid therapy to induce remission. A commonly used regimen of rituximab is 1 g given twice intravenously two weeks apart. Pulsed IV cyclophosphamide 15 mg/kg (IV) every 2–3 weeks for 6–10 doses or oral cyclophosphamide 2 mg/kg/day for 3 months can be used as alternatives. A combination of both agents can be used for those with life-threatening disease. Recent guidelines suggest that moderate-dose glucocorticoids (prednisolone 40–60 mg daily, gradually reducing as the disease comes under control, with the aim of stopping treatment within 6–12 months) is preferable to high-dose glucocorticoids in AAV due to a lower risk of infection. Avacopan 30 mg twice daily can also be used as an adjunct to remission induction therapy as a steroid-sparing measure. Following induction of remission, maintenance therapy with rituximab therapy 1 g every 6 months is recommended. Azathioprine, MTX or MMF can be used as an alternative to rituximab to maintain remission but are less effective. Plasma exchange may be considered as part of the treatment package for those with significant renal impairment (creatinine > 300 µmol/L). For EGPA, cyclophosphamide or rituximab coupled with glucocorticoid therapy should be used for remission-induction as described above. Cyclophosphamide is preferred to rituximab because of the better evidence base. Anti-IL-5 therapy with mepolizumab or benralizumab, a monoclonal antibody directed against the IL-5 receptor (IL-5R), may be of value in maintaining remission and as a steroid-sparing measure, especially when asthma is a predominant feature.

Whatever the subtype, patients with AAV must be followed on a regular and long-term basis since the condition tends to relapse, monitoring urinalysis for blood and protein, plasma creatinine, FBC, ESR, CRP, lung function and PR3 or MPO antibody titres.

Polyarteritis nodosa

Polyarteritis nodosa has a peak incidence between the ages of 40 and 50, with a male-to-female ratio of 2:1. The annual incidence is about 2/1 000 000. Hepatitis B is an important risk factor, and the incidence is 10 times higher in the Inuit of Alaska, in whom hepatitis B infection is endemic. Presentation is with fever, myalgia, arthralgia and weight loss, in combination with manifestations of multisystem disease. The most common skin lesions are palpable purpura, ulceration, infarction and livedo reticularis (see Fig. 25.45). Pathological changes comprise necrotising inflammation and vessel occlusion, and in 70% of patients, arteritis of the vasa nervorum leads to neuropathy, which is typically asymmetrical and affects both sensory and motor function. Severe hypertension and/or renal impairment may occur due to multiple renal infarctions, but glomerulonephritis is rare (in contrast to MPA). The diagnosis is confirmed by conventional or MR angiography, which shows multiple aneurysms and smooth narrowing of mesenteric, hepatic or renal systems, or by muscle or sural nerve biopsy, which reveals the histological changes described above. Initial treatment is with high-dose glucocorticoids and cyclophosphamide followed by a reduction in glucocorticoid dose and introduction of a csDMARD, as described for ANCA-associated vasculitis.

Kawasaki disease

Kawasaki disease is a vasculitis that mostly involves coronary vessels. It presents as an acute systemic disorder, usually affecting children under 5 years. It occurs mainly in Japan and other Asian countries, such as China and Korea, but other ethnic groups may also be affected. Presentation is with fever, generalised rash (including palms and soles), inflamed oral mucosa and conjunctival injection resembling a viral exanthem. The cause is unknown but is thought to be an abnormal immune response to an infectious trigger. A syndrome with some similarities to Kawasaki disease has recently been reported to be a complication of COVID-19 infection in children. Cardiovascular complications include coronary arteritis, leading to myocardial infarction, transient coronary dilatation, myocarditis, pericarditis, peripheral vascular insufficiency and gangrene. Treatment is with aspirin (5 mg/kg daily for 14 days) and IVIg (400 mg/kg daily for 5 days). Ciclosporin (5 mg/kg/day) in combination with IVIg can be effective in patients with resistant disease.

Takayasu arteritis

Takayasu arteritis affects the aorta, its major branches and occasionally the pulmonary arteries. The typical age at onset is 25–30 years, with an 8:1 female-to-male ratio. It has a worldwide distribution but is most common in Asia. It is characterised by granulomatous inflammation of the vessel wall, leading to its occlusion or weakening. It presents with claudication, fever, arthralgia and weight loss. Clinical examination may reveal loss of pulses, bruits, hypertension and aortic incompetence. Investigation typically shows a raised ESR and CRP and a normocytic, normochromic anaemia. The pivotal investigation is CT or MRI angiography, which reveals thickening of the vessel wall and narrowing of the lumen. Aortic coarctation, and aneurysmal dilatation may also occur. The diagnosis can also be made by ^{18}F-fluorodeoxyglucose (FDG) PET-CT imaging, where there is increased tracer uptake in affected vessels. Initial treatment is with high-dose glucocorticoids (40–60 mg daily) in combination with a csDMARD such as azathioprine, MTX or MMF. The dose of glucocorticoid should gradually be reduced with the aim of suppressing inflammatory markers. Vascular imaging may also be employed to assess treatment response. If glucocorticoids and csDMARDs do not give an adequate response, anti-TNF-α or anti IL-6 therapy may be used to maintain control of the disease.

Giant cell arteritis and polymyalgia rheumatica

Giant cell arteritis (GCA) is a granulomatous arteritis that affects medium- and large-sized arteries. It is commonly associated with polymyalgia rheumatica (PMR), which presents with symmetrical pain and stiffness affecting the shoulder and pelvic girdle. There is evidence that these symptoms are due to an inflammatory infiltrate of the synovium and tendon sheaths in the affected regions. Since many patients with GCA have symptoms of PMR, and some patients with PMR go on to develop GCA if untreated, many rheumatologists consider them to be different manifestations of the same underlying disorder. Both diseases are rare under the age of 60 years. The average age at onset is 70, with a female-to-male ratio of about 3:1. The prevalence of GCA in people of European descent is about 20 per 100 000 in those over the age of 50 years, while PMR affect abouts 60 per 100 000. Both conditions are much less common (1 in 100 000) in African and Asian populations. The cause is unknown, but there is a strong genetic component such that GCA is strongly associated with genetic variation at the HLA-DRB1 locus.

Clinical features

The cardinal symptom of GCA is headache, often localised to the temporal or occipital region and accompanied by scalp tenderness. Jaw pain develops in some patients, brought on by chewing or talking, and is referred to as jaw claudication. Visual disturbance can occur (most specifically amaurosis) and a catastrophic presentation is with blindness in one eye due to occlusion of the posterior ciliary artery. In such cases the optic disc may appear pale and swollen with haemorrhages, but these changes may take 24–36 hours to develop and the fundi may initially appear normal. Rarely, neurological involvement may occur, with transient ischaemic attacks, brainstem infarcts and hemiparesis. Constitutional symptoms, such as weight loss, fatigue, malaise and night sweats, may also occur. The GCA probability scoring system (GCAPS) can be useful diagnostically (Box 25.65). If the score is less than 9, GCA is unlikely and further investigations are not required; scores between 9 and 12 indicate possible GCA, whereas scores of > 12 are highly suggestive of GCA.

25.65 GCA probability scoring system

Age	Points	Symptoms	Points
Age < 50	0	Headache	1
Age 50–60	1	Polymyalgia	2
Age 60–65	2	One constitutional symptom	1
Age > 66	3	Two or more constitutional symptoms	3
Sex		**Signs**	
Male	1	Visual signs	3
Female	2	Temporal artery tender	1
Symptom duration		Temporal artery thickened	2
> 24 weeks	0	Temporal artery pulse loss	3
12–24 weeks	1	Other extracranial artery tender	1
6–12 weeks	2	Other extracranial artery thickened	2
< 6 weeks	3	Other extracranial artery pulse loss	3
CRP		Cranial nerve palsy	3
< 5 mg/L	0	**Other potential cause**	
6–10 mg/L	1	Infection, cancer, other pathology	–3
11–25 mg/L	2		
> 25 mg/L	3		

A score of < 9 excludes the diagnosis. Those with scores 9–12 should be referred for further investigations (biopsy or ultrasound) but not started on prednisolone. Those with scores of > 12 should be started on prednisolone and referred for further investigations (see Fig. 25.52).

People with scores above 9 should have further investigations to confirm or exclude GCA (see below).

With PMR, there may be stiffness and painful restriction of active shoulder movements on waking. Sometimes patients can present with symptoms similar to RA. The affected muscles are not tender and there is no weakness or muscle-wasting. Other conditions that cause PMR-like symptoms are shown in Box 25.66.

Investigations

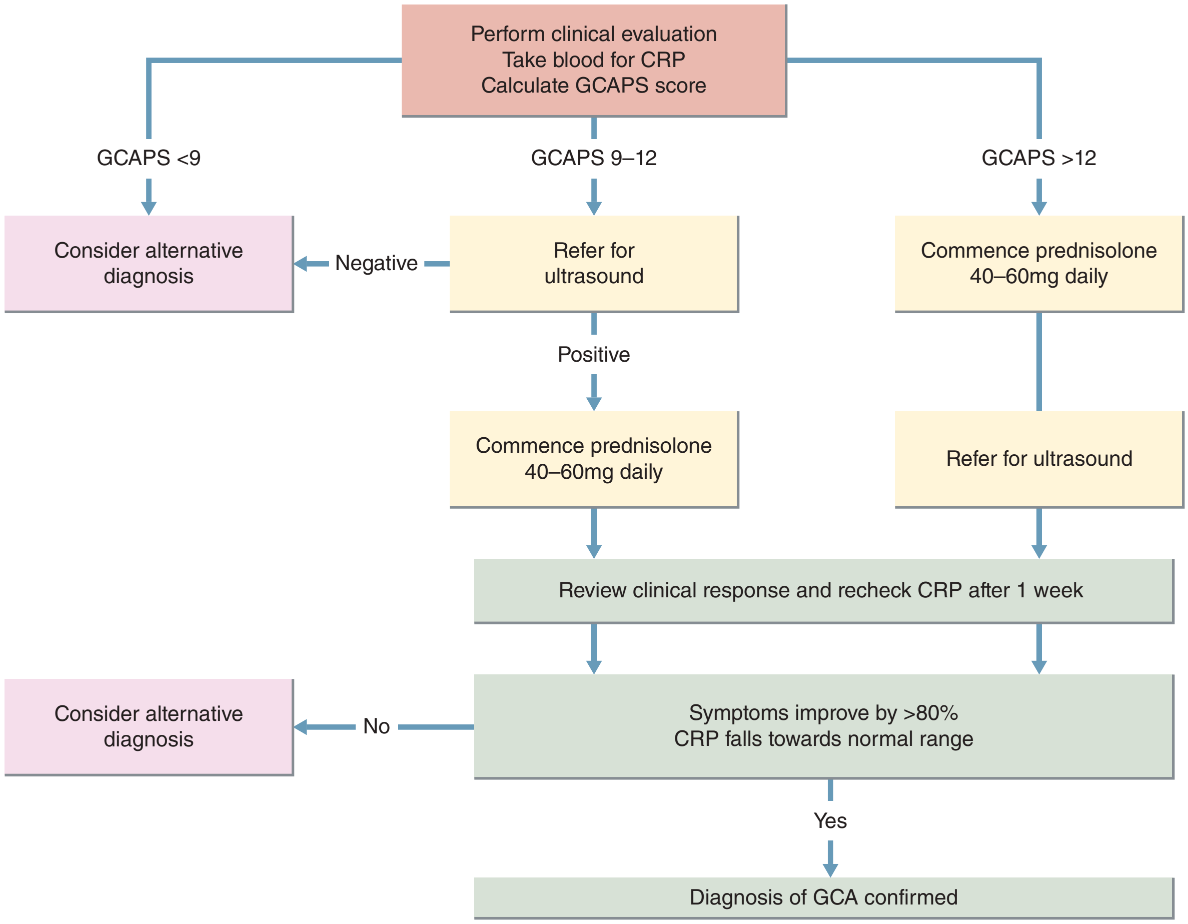
The typical laboratory abnormality is an elevated ESR and CRP, often with normochromic, normocytic anaemia. Abnormal liver function tests may also occur. Very rarely, PMR and GCA can present with a normal ESR in the early stages of disease evolution. Objective evidence for GCA should be obtained whenever possible. The two pivotal investigations are temporal artery biopsy and ultrasound of the temporal arteries. Characteristic biopsy findings are fragmentation of the internal elastic lamina with necrosis of the media in combination with a mixed inflammatory cell infiltrate. The sensitivity is about 70% with multiple biopsies and multiple section analysis (to detect 'skip' lesions). A negative biopsy does not exclude the diagnosis. The characteristic finding on Doppler ultrasound examination is the 'halo' sign, where the thickened vessel wall shows as a dark area surrounding a positive Doppler signal within the vessel. The overall sensitivity is about 55% and specificity about 70% in routine clinical practice. Negative results do not exclude the diagnosis.

25.66 Conditions that can mimic polymyalgia rheumatica

- Calcium pyrophosphate deposition disease
- Spondyloarthritis
- Rheumatoid arthritis
- Psoriatic arthritis (enthesopathic)
- Systemic vasculitis
- Myeloma
- Inflammatory myopathy (particularly inclusion body myositis)
- Lambert–Eaton syndrome
- Osteoarthritis (cervical spondylosis, cervical radiculopathy, bilateral subacromial impingement, facet joint arthritis, osteoarthritis of the acromioclavicular joint)

Management

A suggested algorithm for management of suspected GCA is shown in Figure 25.52. Prednisolone should be commenced immediately in suspected GCA where the GCAPS score is > 12 because of the risk of visual loss pending further investigations. Those with scores of between 9 and 12 should be investigated by ultrasound or temporal artery biopsy but prednisolone should be withheld unless one or other investigation is positive. Patients with scores > 12 and those with scores between 9 and 12 and positive results on investigation should be treated with prednisolone 40–60 mg daily and a review conducted after 1 week. In GCA the response is dramatic, such that symptoms largely resolve within 48–72 hours of starting therapy in virtually all patients. If patients do not respond clinically, another diagnosis should be considered. It is customary to use higher doses in GCA (40–60 mg prednisolone) than in PMR (15–20 mg). In both conditions, the glucocorticoid dose should be progressively reduced, guided by symptoms and CRP or ESR. During treatment, HbA_{1c} should be checked to assess the risk of diabetes mellitus and blood glucose monitoring instituted if values are raised. In GCA the rate of reduction is by 5 mg every 2 weeks until a daily dose of 20 mg is reached, the rate of dose reduction is then reduced to 2.5 mg every 2 weeks until a dose of 10 mg is reached. Subsequently, the dose should



Perform clinical evaluation
Take blood for CRP
Calculate GCAPS score
GCAPS <9
GCAPS 9–12
GCAPS >12
Consider alternative diagnosis
Negative
Refer for ultrasound
Commence prednisolone 40–60mg daily
Positive
Commence prednisolone 40–60mg daily
Refer for ultrasound
Review clinical response and recheck CRP after 1 week
Consider alternative diagnosis
No
Symptoms improve by >80%
CRP falls towards normal range
Yes
Diagnosis of GCA confirmed

Fig. 25.52 Algorithm for management of GCA. (GCAPS = giant cell arteritis probability score; see Sebastian A, et al. under 'Further information')

be reduced by 1 mg/month until a dose of 4 mg has been reached, when adrenal function should be assessed by a random serum cortisol or a short Synacthen test. If adrenal reserve is adequate, treatment can be further reduced and stopped. In PMR, a similar tapering regimen should be used with reductions of 2.5 mg 2-weekly until a dose of 10 mg is reached, followed by further reductions at 1 mg/month. If symptoms recur, inflammatory markers should be checked. If these are elevated, the glucocorticoid dose should be increased to that which previously controlled the symptoms and reduction attempted again in another few weeks. The IL-6 inhibitor tocilizumab and JAK inhibitor upadacitinib have been shown to reduce the risk of relapse following glucocorticoid dose reductions in GCA and are of value in patients at high risk of glucocorticoid side-effects. Standard csDMARDs such as MTX, azathioprine and MMF can also be used as steroid-sparing agents and should be used in patients where it is not possible to reduce the prednisolone dose below 10 mg daily. Most patients need glucocorticoids for an average of 12–24 months, and in view of this, bisphosphonate therapy is almost invariably required to protect against osteoporosis.

IgA vasculitis

IgA vasculitis (previously called Henoch–Schönlein purpura) is a small-vessel vasculitis caused by immune complex deposition following an infectious trigger. It is predominantly a disease of children and young adults. The usual presentation is with purpura over the buttocks and lower legs, accompanied by abdominal pain, gastrointestinal bleeding and arthralgia. Nephritis can also occur and may present up to 4 weeks after the onset of other symptoms. Biopsy of affected tissue shows a vasculitis with IgA deposits in the vessel wall. IgA vasculitis is usually a self-limiting disorder that settles spontaneously without specific treatment. Glucocorticoids and immunosuppressive therapy may be required in patients with more severe disease, particularly in the presence of nephritis.

Cryoglobulinaemic vasculitis

This is a small-vessel vasculitis that occurs when immunoglobulins precipitate out in the cold. Cryoglobulins are classified into three types (see Box 4.17). Types II and III are associated with vasculitis. The typical presentation is with a vasculitic rash over the lower limbs, arthralgia, Raynaud phenomenon and neuropathy. The ESR and CRP are elevated in active disease and C3 levels may be reduced. Some cases are secondary to hepatitis C infection and others are associated with other autoimmune diseases. Affected patients should be screened and, if positive, treated for hepatitis C. There is no consensus as to how best to treat cryoglobulinaemic vasculitis in the absence of an obvious trigger. Glucocorticoids and immunosuppressive therapy are often used empirically, but their efficacy is uncertain. In severe cases, plasmapheresis can be considered.

Behçet disease

This is a vasculitis of unknown aetiology that predominantly targets small arteries and venules but which can affect larger vessels in up to one-third of cases. It is rare in Western Europe but more common in 'Silk Route' countries, around the Mediterranean and in Japan, where there is a strong genetic association with HLA-B51.

Oral ulcers are invariably present (Fig. 25.53). Unlike aphthous ulcers, they are usually deep and multiple, and last for 10–30 days. Genital ulcers are also a common problem, occurring in 60%–80% of cases. The usual skin lesions are erythema nodosum or acneiform lesions, but migratory thrombophlebitis and vasculitis also occur. Ocular involvement is common and may include anterior or posterior uveitis or retinal vasculitis. Neurological involvement occurs in 5% and mainly involves the brainstem, although the meninges, hemispheres and cord can also be affected, causing pyramidal signs, cranial nerve lesions, brainstem symptoms or hemiparesis. Recurrent thromboses also occur.

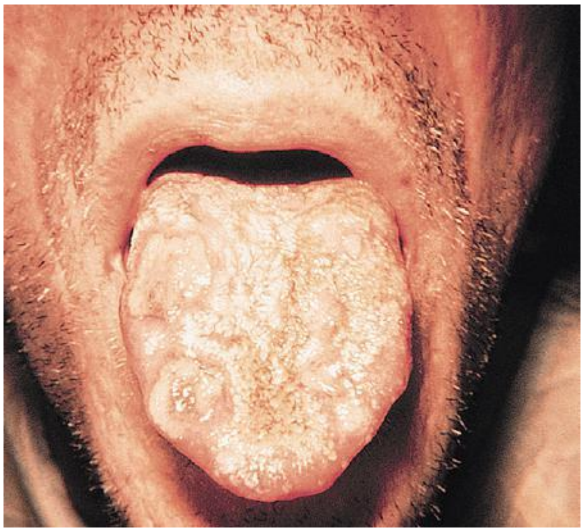


Fig. 25.53 Oral ulceration in Behçet disease.

i 25.67 Criteria for the diagnosis of Behçet disease

Recurrent oral ulceration: minor aphthous, major aphthous or herpetiform ulceration at least three times in 12 months *plus* two of the following:
- Recurrent genital ulceration
- Eye lesions: anterior uveitis, posterior uveitis, cells in vitreous on slit-lamp examination, retinal vasculitis
- Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, acneiform nodules
- Positive pathergy test

The diagnosis is primarily made on clinical grounds (Box 25.67), but one characteristic feature that can be of diagnostic value is the pathergy test, which involves pricking the skin with a needle and looking for evidence of pustule development within 48 hours.

Oral and genital ulceration can be managed with a combination of colchicine and topical glucocorticoid preparations. Colchicine can be effective for erythema nodosum and arthralgia. Glucocorticoids and immunosuppressants such as azathioprine are indicated for uveitis, recurrent venous thrombosis and neurological disease. Anti-TNF-α therapy and/or thalidomide may be required in refractory patients.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory disease of cartilage that classically presents with acute pain and swelling of one or both ear pinnae, sparing the lower non-cartilaginous portion. Around 30% of patients have coexisting autoimmune or connective tissue disease. Involvement of tracheobronchial cartilage may lead to hoarseness, cough, stridor or expiratory wheeze. Other manifestations include collapse of the bridge of the nose, scleritis, hearing loss and cardiac valve dysfunction. Cartilage biopsy shows an inflammatory infiltrate in the perichondrium. Both ESR and CRP are raised in active disease. Pulmonary function tests, including flow–volume loops, should be performed to assess the degree of laryngotracheal disease, since this is an important cause of mortality. Mild disease usually responds to low-dose glucocorticoids or NSAIDs, whereas major tracheobronchial involvement requires high-dose glucocorticoids and immunosuppressants, as described for SLE.

IgG4 disease

This is a rare condition (1–3/100 000) characterised by an inflammatory infiltrate of affected tissues in the early stages followed by fibrotic damage as the disease progresses. The disease may present in many ways, including with swelling of the lacrimal and salivary glands (mimicking Sjögren disease) and proptosis, sinusitis, hearing loss, interstitial lung disease and cranial nerve lesions (mimicking GPA). Inflammatory disease of the great vessels may occur, while abdominal pain may result from infiltration of the pancreas or retroperitoneum. Thyroid involvement may manifest as Hashimoto thyroiditis and Riedel thyroiditis. The diagnosis can be confirmed by the presence of a lymphocytic infiltrate on tissue biopsy, rich in IgG4-secreting plasma cells, and a raised serum IgG4. Management is with glucocorticoids (prednisolone 30–40 mg/day with progressive dose reduction guided by symptoms, inflammatory markers and IgG4 levels) and a csDMARD such as MTX, azathioprine or MMF. Intravenous rituximab has also been used successfully, using a similar regimen as in RA.

VEXAS syndrome

The VEXAS syndrome (*V*acuoles, *E*1 enzyme, *X*-linked, *A*utoinflammatory, *S*omatic) is a rare disease of adulthood caused by somatic loss-of-function pathogenic variants in *UBA1*, which is located on the X-chromosome. It principally affects men. The gene product encodes an enzyme responsible for cellular ubiquitylation. These variants disturb intracellular signalling in a variety of cell types leading to an autoinflammatory disorder with involvement of the skin, lungs, blood vessels and cartilage. It can mimic systemic vasculitis or relapsing polychondritis. Haematological abnormalities including macrocytic anaemia, thrombocytopenia, thromboembolic disease, and progressive bone marrow failure may occur. The diagnosis should be considered in patients with treatment-refractory inflammatory disease with haematological abnormalities. The diagnosis is suspected on finding vacuoles in myeloid and erythroid progenitor cells in bone marrow aspirates and can be confirmed by genetic analysis of bone marrow or peripheral blood for the causal variants. Various treatments have been tried with varying success including high-dose steroids, anti-TNF or anti-IL-6 therapy, JAK inhibitors and azacytidine. Even with treatment, the 5-year mortality is about 60%.

Diseases of bone

Osteoporosis

Osteoporosis is the most common bone disease. It has been estimated that more than 8.9 million fractures occur annually worldwide and most of these occur in patients with osteopenia or osteoporosis. About one-third of all women and one-fifth of men aged 50 and above suffer fractures at some point in life. The burden of osteoporosis-related fractures is predicted to increase by two- to threefold by 2050 on a worldwide basis, due to ageing of the population. Osteoporosis is under-diagnosed and under-treated throughout Asia, particularly in rural areas, due to low provision of technologies like DXA, which are required to make the diagnosis. Osteoporosis-related fractures can affect any bone, but common sites are the forearm (Colles fracture), spine (vertebral fractures), humerus and hip. These fractures become more common with increasing age (Fig. 25.54). Since only about one-third of vertebral fractures come to medical attention (clinical vertebral fractures), the true number of patients with vertebral fracture is likely to be much greater than that shown in Figure 25.54. Hip fractures are the most serious complication of osteoporosis and have an immediate mortality of about 12% and a continued increase in mortality of about 20% when compared with age-matched controls. Treatment of hip fracture accounts for most of the health-care costs associated with osteoporosis.

Pathophysiology

The defining feature of osteoporosis is reduced bone density, which causes micro-architectural deterioration of bone tissue and leads to an increased risk of fracture, in response to minor trauma. The risk of fracture increases markedly with age in both genders (see Fig. 25.54). This is mostly attributable to an increased risk of falling with age but is also due in part to an age-related decline in bone density, especially in women (Fig. 25.55). Bone mass increases during growth to reach a peak between the ages of 20 and about 45 years but falls thereafter in both genders

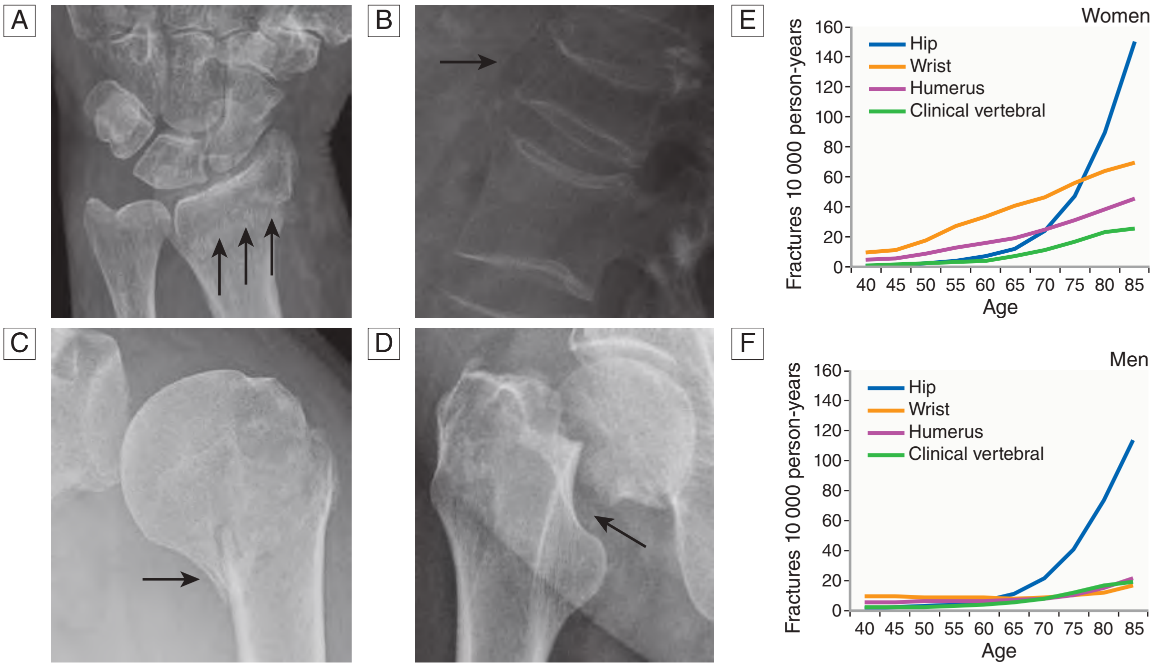

Fig. 25.54 Fractures associated with osteoporosis. A Wrist. B Vertebrae. C Humerus. D Hip. The fracture sites are indicated by black arrows. E and F The changing incidence of each of these fractures with age in women and men, respectively. *From Curtis EM, van der Velde R, Moon RJ, et al. Epidemiology of fractures in the United Kingdom, 1988–2012: variation with age, sex, geography, ethnicity and socioeconomic status. Bone 2016;87:19–26.*

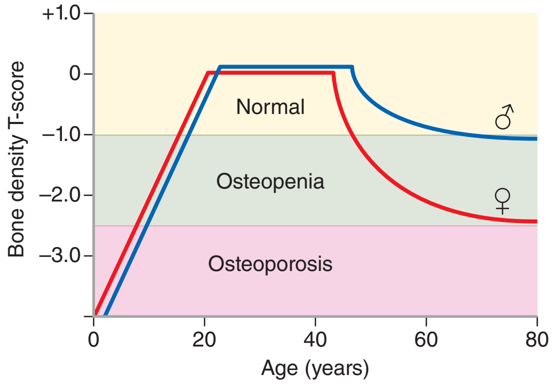

Fig. 25.55 Changes in bone mass with age. Changes in men (blue line) and women (red line).

with an accelerated phase of bone loss after the menopause in women due to oestrogen deficiency. The loss of bone with ageing is caused by an imbalance in the bone remodelling cycle, whereby the amount of new bone formed by osteoblasts cannot keep pace with the amount that is removed by osteoclasts (see Fig. 25.2). The reduction in bone formation is thought to be partly due to differentiation of bone marrow stem cells to adipocytes, as opposed to osteoblasts. Osteoporosis sometimes occurs because of failure to attain adequate levels of peak bone mass but is more commonly due to bone loss as the result of increasing age, inflammatory disorders or the drugs used to treat these disorders.

There are a wide variety of risk factors for osteoporosis, as summarised in Box 25.68. Genetic factors account for up to 80% of variation in bone density, and genome-wide association studies have shown that susceptibility is determined in part by a large number of common variants, some of which are involved in the RANK and Wnt signalling pathways (see Fig. 25.2). Rarely, osteoporosis may be caused by pathogenic variants in single genes including *LRP5* and *WNT1*. Environmental factors, such as exercise and calcium intake during growth and adolescence, are important in maximising peak bone mass and in regulating rates of post-menopausal bone loss. Smoking has a detrimental effect on BMD and is associated with an increased fracture risk, partly because female smokers have an earlier menopause than non-smokers. Heavy alcohol intake is a recognised cause of osteoporosis and fractures, but moderate intake does not substantially alter risk.

Idiopathic osteoporosis

The term idiopathic osteoporosis is frequently used to describe the occurrence of osteoporosis in patients with no specific underlying cause. It is slightly misleading, since most, if not all, patients in this category have age-related osteoporosis or osteoporosis associated with inheritance of genetic variants that regulate bone density.

Secondary osteoporosis

Osteoporosis can occur in association with a variety of diseases and drug treatments, and in many cases more than one disease or risk factor is operative. The most important causes are summarised in Box 25.68. Secondary causes of osteoporosis are particularly common in men, occurring in up to 50% of patients. Hypogonadism, glucocorticoid use (see below) and alcohol excess are the most important predisposing factors.

Glucocorticoid-induced osteoporosis

Glucocorticoid-induced osteoporosis is a common problem in patients with systemic inflammatory and chronic pulmonary diseases. The risk of osteoporosis is related to dose and duration of glucocorticoid therapy and increases substantially in patients who have taken more than 7.5 mg of prednisolone daily for more than 3 months (or an equivalent dose of another glucocorticoid). Inhaled glucocorticoids can reduce bone density, but the risk of osteoporosis is much lower than with systemic therapy. Glucocorticoids mainly cause osteoporosis by inhibiting bone formation and causing apoptosis of osteoblasts and osteocytes. Other contributory mechanisms include inhibition of intestinal calcium absorption, increased renal excretion of calcium and secondary hyperparathyroidism, which stimulates osteoclastic bone resorption.

25.68 Risk factors for osteoporosis

Genetics

- Single-gene disorders:
- Pathogenic variants in *LRP5, WNT1 or ESR*
- Polygenic inheritance:
- Common variants in many pathways

Endocrine disease

- Hypogonadism
- Hyperthyroidism
- Hyperparathyroidism
- Cushing syndrome

Inflammatory disease

- Inflammatory bowel disease
- Ankylosing spondylitis
- Rheumatoid arthritis

Drugs

- Glucocorticoids
- Gonadotrophin-releasing hormone (GnRH) agonists
- Levothyroxine over-replacement
- Heparin
- Aromatase inhibitors
- Thiazolidinediones
- Anticonvulsants
- Alcohol intake > 3 U/day

Gastrointestinal disease

- Malabsorption
- Chronic liver disease

Lung disease

- Chronic obstructive pulmonary disease
- Cystic fibrosis

Miscellaneous

- Myeloma
- Homocystinuria
- Anorexia nervosa*
- Highly trained athletes*
- HIV infection
- Gaucher disease
- Systemic mastocytosis
- Immobilisation
- Low body mass index
- Heavy smoking
- Autoantibodies to osteoprotegerin (OPG)

*Hypogonadism also plays a role in osteoporosis associated with these conditions.
(*ESR* = oestrogen receptor; HIV = human immunodeficiency virus; *LRP5* = low-density lipoprotein receptor-related protein 5; *WNT1* = wingless-type MMTV integration site family, member 1)

Pregnancy-associated osteoporosis

This is a rare form of osteoporosis that typically presents with back pain and multiple vertebral fractures usually during the third trimester or puerperium. It is discussed in more detail in Chapter 30.

Clinical features

Osteoporosis does not cause symptoms until a fracture occurs. Non-vertebral fractures are almost always caused by a traumatic event, most usually a simple fall. The term ‘fragility fracture’ is used to describe a fracture that occurs as the result of a fall from standing height or less. These are typical of osteoporosis. It is important to remember that most people who suffer a fragility fracture do not have osteoporosis; some have normal BMD, but most have osteopenia (Fig. 25.56). The clinical signs of fracture are pain, local tenderness and deformity. In hip fracture, the patient (with rare exceptions) is unable to weight-bear and has a shortened and externally rotated limb on the affected side. The presentation of vertebral fractures is variable. Some patients present with acute severe back pain. This may radiate to the anterior chest or abdominal wall and be mistaken for a myocardial infarction, aortic dissection or intra-abdominal pathology. In others the presentation is with height loss and kyphosis in the absence of pain or with chronic back pain. Osteoporosis may be

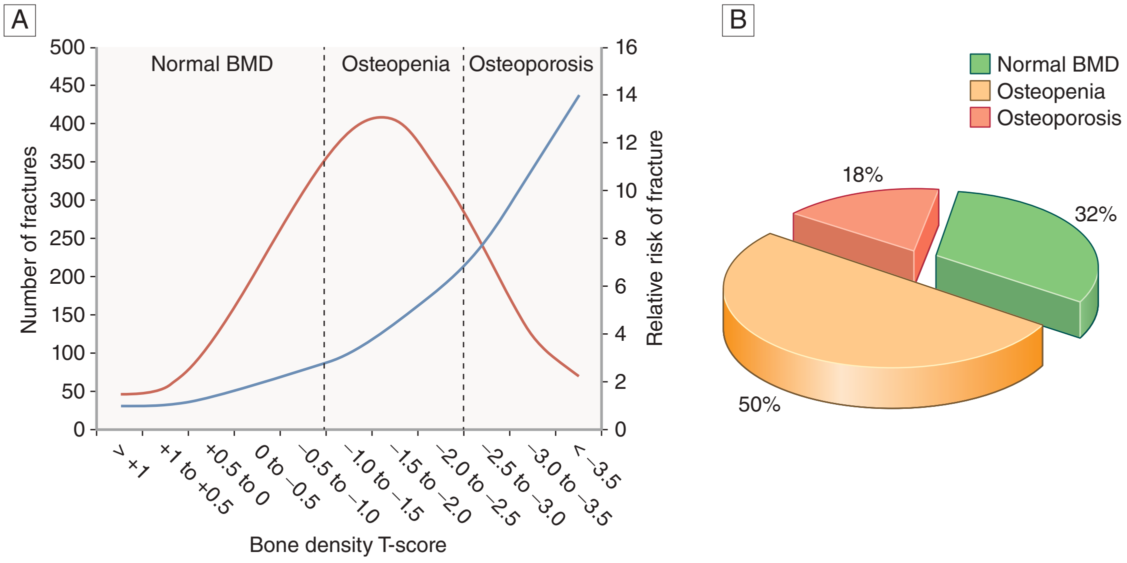

Fig. 25.56 **Relation between bone mineral density (BMD) and fractures.** **A** The relative risk of fracture increases exponentially as BMD falls (blue line) and is 14-fold higher in people with a T-score of < −3.5 compared with those with normal BMD. In absolute terms, however, more fractures occur in people with normal BMD or osteopenia (red line). **B** The number of fractures that occur in people with normal BMD, osteopenia and osteoporosis.

i 25.69 Indications for dual X-ray absorptiometry (DXA)

- Low-trauma fracture, age > 50 years
- Clinical risk factors and 10-year fracture risk > 10%
- Glucocorticoid therapy (> 7.5 mg prednisolone daily for > 3 months)
- Baseline and follow-up assessment of response of osteoporosis to treatment
- Assessment of progression of osteopenia to osteoporosis
- Age < 50 years and strong risk factors for osteoporosis

suspected by the finding of radiological osteopenia or vertebral deformities on imaging that has been performed for other reasons.

Investigations

The most important investigation is DXA (see Figs. 25.8 and 25.57). This should be considered in patients aged over 50 who have already suffered a fragility fracture, and in those with clinical risk factors (Box 25.69) when a fracture risk assessment tool has returned an elevated value. The risk at which DXA should be performed remains a subject of debate, but a 10-year risk of fracture of > 10% has been suggested, since there is evidence of benefit from treatment at this level. Other indications for DXA are in patients under 50 who have very strong risk factors, such as premature menopause or high-dose glucocorticoids. Figure 25.57 provides a suggested algorithm for the investigation of patients with suspected osteoporosis.

A history should be taken to identify any predisposing causes, such as early menopause, excessive alcohol intake, smoking and glucocorticoid therapy. Signs of endocrine disease, neoplasia and inflammatory disease should be sought on clinical examination. A falls history should be taken and screening tests performed to assess the risk of falls (p. 1339). Screening for secondary causes of osteoporosis should be performed, as summarised in Box 25.70.

Management

The aim of treatment is to reduce the risk of fracture, and this can be achieved by a combination of approaches.

Non-pharmacological interventions

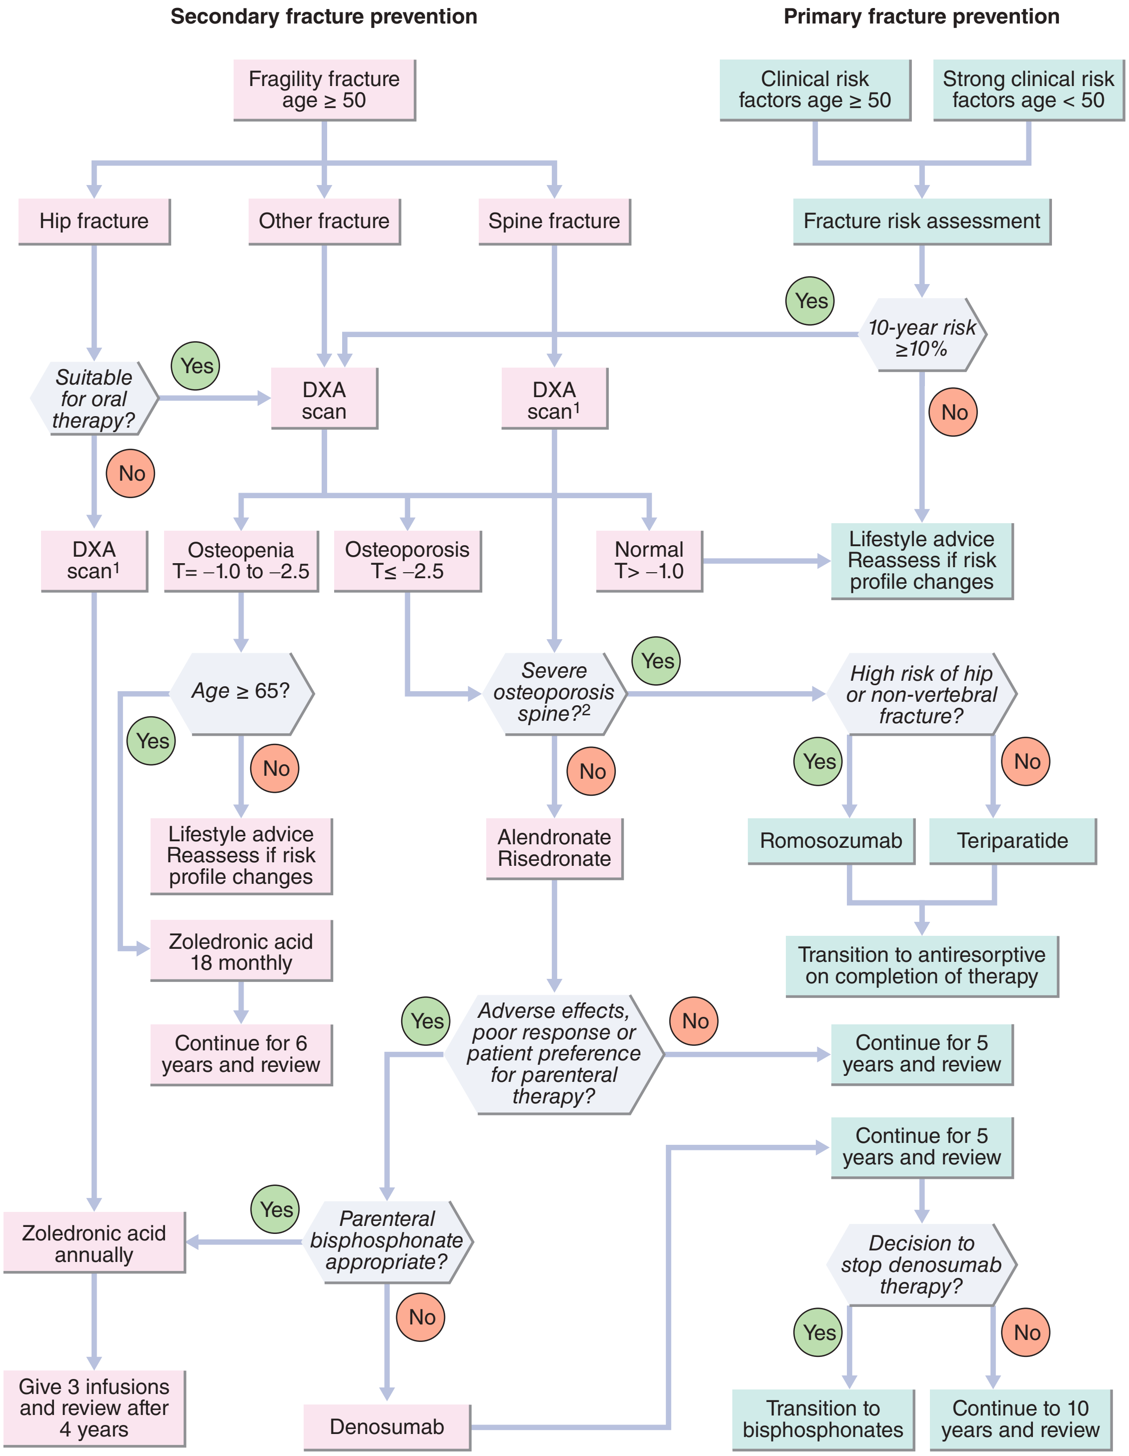
Advice on smoking cessation, moderation of alcohol intake, adequate dietary calcium intake and exercise should be given. Those with recurrent falls or unsteadiness on a 'get up and go' test (p. 1339) should be referred to a multidisciplinary falls-prevention team. Hip protectors can reduce the risk of hip fracture in selected patients, but adherence is often poor.

Pharmacological interventions

Several drug treatments are now available to reduce the risk of fracture in osteoporosis. The dosages, mode of administration and indications are summarised in Box 25.71. More detail on the individual drugs is provided below.

Bisphosphonates Bisphosphonates are the first-line treatment for mild to moderate osteoporosis. These are a class of drugs with a central core of P-C-P atoms, to which various sidechains can be attached. Following administration, they target bone surfaces and are ingested by osteoclasts during the process of bone resorption. The bisphosphonate is released within the osteoclast, causing cell death and thereby inhibiting bone resorption. Bone density increases but this is principally due to increased mineralisation of existing bone, rather than an increase in bone mass (Fig. 25.58). Bisphosphonates reduce the risk of fractures in osteoporosis, but do not completely prevent the occurrence of fractures.

Oral bisphosphonates are typically given for a period of 5 years, at which point the need for continued therapy should be evaluated, with a repeat DXA if possible. If patients have remained free of fractures after 5 years and if BMD levels have increased and no longer remain in the osteoporotic range, a 3- to 5-year drug holiday can be given. Treatment may be continued for up to 10 years in patients whose BMD levels remain in the osteoporotic range after 5 years and in those with pre-existing vertebral fractures. Continuous treatment beyond 10 years is not advisable due to the risk of over-suppressing bone remodelling with an increased likelihood of atypical femoral fractures and osteonecrosis of the jaw (see below). A change in oral bisphosphonate treatment should be considered in patients who have lost BMD despite adhering to therapy (more than 4% at any site). Most commonly, this will be a switch to parenteral zoledronic acid (ZA) which is often given by annual infusion of 5 mg for 3 consecutive years followed by a spell of 3–4 years without treatment. Infusions every 18 months over a spell of 6 years have also been found to be effective for fracture prevention in post-menopausal women with osteopenia aged > 65. With this regimen, treatment can be recommenced 3 years after the final infusion if BMD remains in the osteopenic range. Intravenous ZA has also been shown to be effective



Secondary fracture prevention

at preventing recurrent fractures in elderly patients following hip fracture and to improve mortality in this patient group (Box 25.72).

Oral bisphosphonates are poorly absorbed from the gastrointestinal tract and should be taken on an empty stomach with plain water; no food should be eaten for 30–45 minutes after administration. They are contraindicated in patients with oesophageal stricture or achalasia, since the tablets may stick in the oesophagus, causing ulceration and perforation. Bisphosphonates are also contraindicated in people with impaired renal function (eGFR <30 for risedronate and <35 for other bisphosphonates). Upper gastrointestinal upset occurs in about 5% of cases. Oral bisphosphonates can be used in patients with gastro-oesophageal reflux disease but may cause worsening of symptoms. The most common adverse effect with intravenous bisphosphonates is a transient influenza-like illness with fever, malaise, anorexia and generalised aches and pains, which occurs 24–48 hours after administration (the acute phase response or APR). It predominantly occurs after the first exposure but tolerance develops thereafter. The APR is self-limiting but can be treated with paracetamol or NSAIDs if severe. Oral dexamethasone 4 mg orally just before and for 3 days after IV zoledronic acid has been found to reduce the risk of the APR occurring. Other adverse effects are shown in Box 25.73. Osteonecrosis of the jaw is characterised by the presence of necrotic bone in the mandible or maxilla, typically occurring after tooth extraction when the socket fails to heal. This complication is very rare in osteoporosis, but patients receiving bisphosphonates should be advised to have regular dental checkups and pay attention to good oral hygiene. There is no evidence that temporarily stopping bisphosphonates for tooth extraction alters the risk of osteonecrosis of the jaw. Atypical subtrochanteric fractures have been described in patients who have received long-term bisphosphonates and appear to be the result of over-suppression of normal bone remodelling. In the vast majority, the benefits of bisphosphonate therapy far outweigh the risks, but it is important for treatment to be targeted to patients with low BMD who are most likely to benefit.

Denosumab Denosumab is a monoclonal antibody that inhibits bone resorption by neutralising the effects of RANKL (see Fig. 25.2). It is administered by subcutaneous injection of 60 mg every 6 months in the treatment of osteoporosis and has similar efficacy to zoledronic acid. One potential adverse effect is hypocalcaemia, but this can be mitigated by calcium and vitamin D supplements. Denosumab may rarely cause osteonecrosis of the jaw and atypical subtrochanteric fractures. When denosumab is stopped, there is a rebound increase in bone turnover that can be associated with an increased risk of vertebral fracture and even hypercalcaemia. Because of this, denosumab needs to be continued on a long-term basis; if it must be stopped for any reason, oral or IV bisphosphonate therapy should be given to inhibit the rebound increase in bone turnover.

Calcium and vitamin D Combined calcium and vitamin D supplements have limited efficacy in the prevention of osteoporotic fractures when given alone but are widely used as an adjunct to other treatments. A typical daily dosage is 1000 mg calcium and 800 IU vitamin D. Calcium and vitamin D supplements have efficacy in preventing fragility fractures in old age or in institutionalised patients, who are at high risk of classical vitamin D deficiency (see Box 25.74). Vitamin D supplements alone do not

i 25.70 Investigations to consider in suspected osteoporosis

Investigation	Secondary cause of osteoporosis
Urea, creatinine and electrolytes	Chronic kidney disease
Liver function tests and albumin	Chronic liver disease
Full blood count, erythrocyte sedimentation rate	Inflammatory disease Myeloma
Tissue transglutaminase antibodies	Coeliac disease
Serum calcium and phosphate, 25(OH)D, PTH	Primary and secondary hyperparathyroidism, vitamin D deficiency
Thyroid function tests	Hyperthyroidism
Serum protein electrophoresis	Myeloma Monoclonal gammopathy of uncertain significance
Urine Bence Jones protein	Myeloma
Testosterone and gonadotrophins	Male hypogonadism
Oestrogen and gonadotrophins	Female hypogonadism[1]
Bone biopsy	Unexplained early-onset osteoporosis[2]

25.72 Osteoporosis in old age

- **Bone loss**: due to increased bone turnover, with an age-related defect switch in differentiation of bone marrow stromal cells to form adipocytes as opposed to osteoblasts.
- **Fractures due to osteoporosis**: common cause of morbidity and mortality, although fracture healing is not delayed by age.
- **Recurrent fractures**: those who suffer a fragility fracture are at increased risk of further fracture, so should be investigated for osteoporosis and treated if this is confirmed.
- **Falls**: risk factors for falls (such as visual and neuromuscular impairments) are independent risk factors for hip fracture in older people, so intervention to prevent falls is as important as treatment of osteoporosis.
- **Intravenous zoledronic acid**: reduces mortality and subsequent fracture in selected older patients with hip fractures.
- **Calcium and vitamin D**: reduce the risk of fractures in those who are housebound or living in care homes.

25.73 Adverse effects of bisphosphonates

Common

- Upper gastrointestinal intolerance (oral)
- Acute phase response (intravenous)

Less common

- Atrial fibrillation (intravenous zoledronic acid)
- Hypocalcaemia (intravenous bisphosphonates)
- Musculoskeletal pain

Rare

- Uveitis
- Osteonecrosis of the jaw
- Oesophageal ulceration
- Atypical subtrochanteric fracture
- Acute kidney injury

prevent fractures in osteoporosis, but there is evidence that the response to bisphosphonates is blunted in patients with vitamin D deficiency. If the patient's dietary calcium is sufficient, stand-alone vitamin D supplements (800 IU daily) can be prescribed as an adjunct to anti-osteoporosis therapies. Calcitriol (1,25(OH)$_2$D$_3$), the active metabolite of vitamin D, is licensed for treatment of osteoporosis, but it is seldom used because the data on fracture prevention are less robust than for other agents.

Teriparatide Teriparatide (TPTD) is the 1-34 fragment of human PTH. It is an effective treatment for osteoporosis, which works by stimulating new bone formation. While TPTD also stimulates bone resorption, the increase in bone formation is greater, increasing bone density, particularly at the spine. It is given by a self-administered subcutaneous injection in a dose of 20 µg daily for 2 years. At the end of this period, an inhibitor of bone resorption (typically bisphosphonate therapy) should be administered to maintain the increase in BMD. Oral bisphosphonates and TPTD should not be given in combination, since the bisphosphonate blunts the anabolic effect. The efficacy of TPTD for prevention of non-vertebral fractures is similar to that of oral bisphosphonates, but it is superior in preventing vertebral fractures. The most common adverse effects are headache, muscle cramps and dizziness. Mild hypercalcaemia may occur, but it is usually asymptomatic and does not require discontinuation of treatment. Monitoring of serum calcium is not required during TPTD treatment.

Abaloparatide Abaloparatide is the 1-34 fragment of PTH-related protein, which has effects similar to those of TPTD. It is given as a self-administered injection of 80 µg daily for 18 months. At the end of this period, an inhibitor of bone resorption should be given to maintain the increase in bone mass. Efficacy has been demonstrated for the prevention of vertebral fractures.

Romosozumab This is a neutralising antibody to sclerostin, which is produced by osteocytes and acts to inhibit bone formation as well as to stimulate bone resorption (see Fig. 25.2). Romosozumab is a highly

25.74 Causes of osteomalacia and rickets

Cause	Predisposing factor	Mechanism
Vitamin D deficiency		
Classical	Lack of sunlight exposure and poor diet	Reduced cholecalciferol synthesis in the skin/low levels of vitamin D in the diet
Gastrointestinal disease	Malabsorption	Malabsorption of dietary vitamin D and calcium
Failure of 1,25 vitamin D synthesis		
Chronic renal failure	Hyperphosphataemia and kidney damage	Impaired conversion of 25(OH)D to 1,25(OH)$_2$D
Vitamin D-resistant rickets type I (autosomal recessive)	Loss-of-function variants in renal 25(OH)D 1α-hydroxylase enzyme	Impaired conversion of 25(OH)D to 1,25(OH)$_2$D
Vitamin D receptor defects		
Vitamin D-resistant rickets type II (autosomal recessive)	Loss-of-function variants in vitamin D receptor	Impaired response to 1,25(OH)$_2$D
Defects in phosphate and pyrophosphate metabolism		
Hypophosphataemic rickets (X-linked dominant)	Pathogenic variants in *PHEX*	Increased FGF23 production (mechanism unclear)
Autosomal dominant hypophosphataemic rickets	Pathogenic variants in *FGF23*	Mutant FGF23 is resistant to degradation
Autosomal recessive hypophosphataemic rickets	Pathogenic variants in *DMP1*	Increased production of FGF23. Local deficiency of DMP1 inhibits mineralisation
Tumour-induced hypophosphataemic osteomalacia	Ectopic production of FGF23 by tumour	Over-production of FGF23
Hypophosphatasia	Pathogenic variants in *ALPL*, which encodes alkaline phosphatase	Inhibition of bone mineralisation due to accumulation of pyrophosphate in bone
Iatrogenic and other causes		
Bisphosphonate therapy	High-dose etidronate/pamidronate	Drug-induced impairment of mineralisation
Aluminium	Use of aluminium-containing phosphate binders or aluminium in dialysis fluid	Aluminium-induced impairment of mineralisation
Fluoride	High fluoride in water	Inhibition of mineralisation by fluoride

(FGF23 = fibroblast growth factor 23)

effective treatment for osteoporosis and works by inhibiting bone resorption and stimulating bone formation. It is indicated for the treatment of severe osteoporosis particularly in patients with vertebral fractures, where it is given by self-administered subcutaneous injection 210 mg once a month for 12 months. Following completion of treatment, an inhibitor of bone resorption should be given to maintain the increase in bone density. Romosozumab is significantly more effective than oral alendronic acid at preventing fractures of all types and it is one of the most effective treatments for osteoporosis currently available. Adverse effects are uncommon, although a slight excess of cardiovascular events was observed in some clinical trials and because of that it is contraindicated in patients with a previous history of myocardial infarction or stroke.

Hormone replacement therapy Cyclical HRT with oestrogen and progestogen prevents post-menopausal bone loss and reduces the risk of vertebral and non-vertebral fractures in post-menopausal women. It is primarily indicated for the prevention of osteoporosis in women with an early menopause and for treatment of women with osteoporosis who are in their early fifties and who have troublesome menopausal symptoms. It is not recommended above the age of 60 because of an increased risk of breast cancer, cardiovascular disease and venous thromboembolism.

Raloxifene Raloxifene is a selective oestrogen receptor modulator (SERM) that acts as a partial agonist at oestrogen receptors in bone and liver, but as an antagonist in breast and endometrium. It is effective in reducing the risk of vertebral fractures but does not influence the risk of non-vertebral fracture and is seldom used. Adverse effects include muscle cramps, worsening of hot flushes and an increased risk of venous thromboembolism. Bazedoxifene is a related SERM that has similar effects to raloxifene.

Tibolone Tibolone has partial agonist activity at oestrogen, progestogen and androgen receptors. It has been shown to prevent vertebral and non-vertebral fractures in post-menopausal osteoporosis. Treatment is associated with a slightly increased risk of stroke, but a reduced risk of breast cancer.

Surgery

Orthopaedic surgery with internal fixation is frequently required to reduce and stabilise osteoporotic fractures. Patients with intracapsular fracture of the femoral neck generally need hemi-arthroplasty or total hip replacement in view of the high risk of osteonecrosis.

Vertebroplasty is sometimes used in the treatment of painful vertebral compression fractures. It involves injecting methyl methacrylate (MMA) into the affected vertebral body under sedation and local anaesthesia. Randomised trials have shown no benefit as compared with a sham procedure. Kyphoplasty is used under similar circumstances, but in this case a needle is introduced into the affected vertebral body and a balloon is inflated, which is then filled with MMA. It has similar efficacy to vertebroplasty. Serious adverse effects may occur with both procedures, including spinal cord compression due to leakage of MMA, and neither procedure is recommended.

Osteomalacia, rickets and vitamin D deficiency

Osteomalacia and rickets are characterised by defective mineralisation of bone. The most common cause is vitamin D deficiency, but both conditions can also occur as the result of inherited defects in renal phosphate excretion, inherited defects in the vitamin D receptor and in the pathways responsible for vitamin D activation. Other causes are summarised in Box 25.74 and are discussed in more detail below. The term osteomalacia refers to the syndrome when it occurs in adults; rickets is the equivalent in children.

Vitamin D deficiency

Vitamin D deficiency is a biochemical diagnosis, which is defined to be present when serum 25(OH)D concentrations are below 25 nmol/L (10 ng/mL). People with vitamin D levels in the range 25–50 nmol/L (10–20 ng/mL) are said to have vitamin D insufficiency, whereas those with 25(OH)D levels above 50 nmol/L (20 ng/mL) are classified as having normal vitamin D status. The likelihood of developing vitamin D deficiency is strongly related to sunlight exposure. It is common in northern latitudes (or southern latitudes in the southern hemisphere) and shows seasonal variation. Vitamin D deficiency is more common in the winter and spring and less common in summer and autumn (for a UK example, see Fig. 25.59). People with dark skin and those who wear facial coverings are more prone to developing vitamin D deficiency.

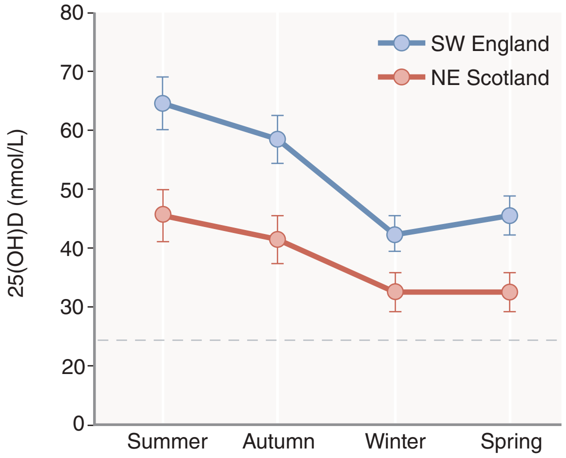

Fig. 25.59 Seasonal changes in vitamin D concentrations. (To convert nmol/L to ng/mL, multiply by 2.5.) *Adapted from McDonald HM, Mavroeidi A, Fraser WD, et al. Sunlight and dietary contributions to the seasonal vitamin D status of cohorts of healthy postmenopausal women living at northerly latitudes: a major cause for concern? Osteoporosis Int 2011;22:2461–2472.*

Pathogenesis

The source of vitamin D and pathways involved in regulating its metabolism are shown in Figure 25.60. In normal individuals, vitamin D (also known as cholecalciferol) comes from two sources: about 70% is made in the skin, where 7-dehydrocholesterol is converted to cholecalciferol under the influence of ultraviolet light, whereas the remaining 30% is derived from the diet. The main dietary sources are oily fish and meat, although bread and dairy products are fortified with vitamin D in some countries. On entering the circulation, vitamin D is hydroxylated in the liver to form 25(OH)D, and this is further hydroxylated in the kidney to form $1,25(OH)_2D$, the biologically active metabolite. The $1,25(OH)_2D$ primarily acts on the gut to increase intestinal calcium absorption, but also acts on the skeleton to stimulate bone remodelling. Synthesis of $1,25(OH)_2D$ is regulated by a negative feedback loop orchestrated by the parathyroid glands. When vitamin D levels fall – as the result of lower sunlight exposure or dietary lack – production of $1,25(OH)_2D$ is reduced, causing a reduction in calcium absorption from the gut. This causes a transient fall in serum calcium, which is detected by calcium-sensing receptors on the parathyroid chief cells; this increases PTH secretion, which restores calcium levels to normal. Vitamin D deficiency is, therefore, usually characterised by a low level of 25(OH)D and a raised level of PTH. Sometimes, low 25(OH)D levels may be observed in the presence of a normal PTH concentration. This is of uncertain clinical significance and can be due to variations in levels of vitamin D-binding protein. Serum concentrations of vitamin D are under genetic control and are associated with variants close to the *GC* gene, which encodes vitamin D-binding protein; the *DHCR7* gene, which encodes 7-dehydrocholesterol reductase, responsible for catalysing conversion of 7-DHC to cholesterol; the *CYP2R1* gene, which encodes vitamin D-25-hydroxylase, responsible for hydroxylation of vitamin D in the liver; and the *CYP24A1* gene, which encodes vitamin D-24-hydroxylase, responsible for converting 25(OH)D to the inactive metabolite $24,25(OH)_2D$.

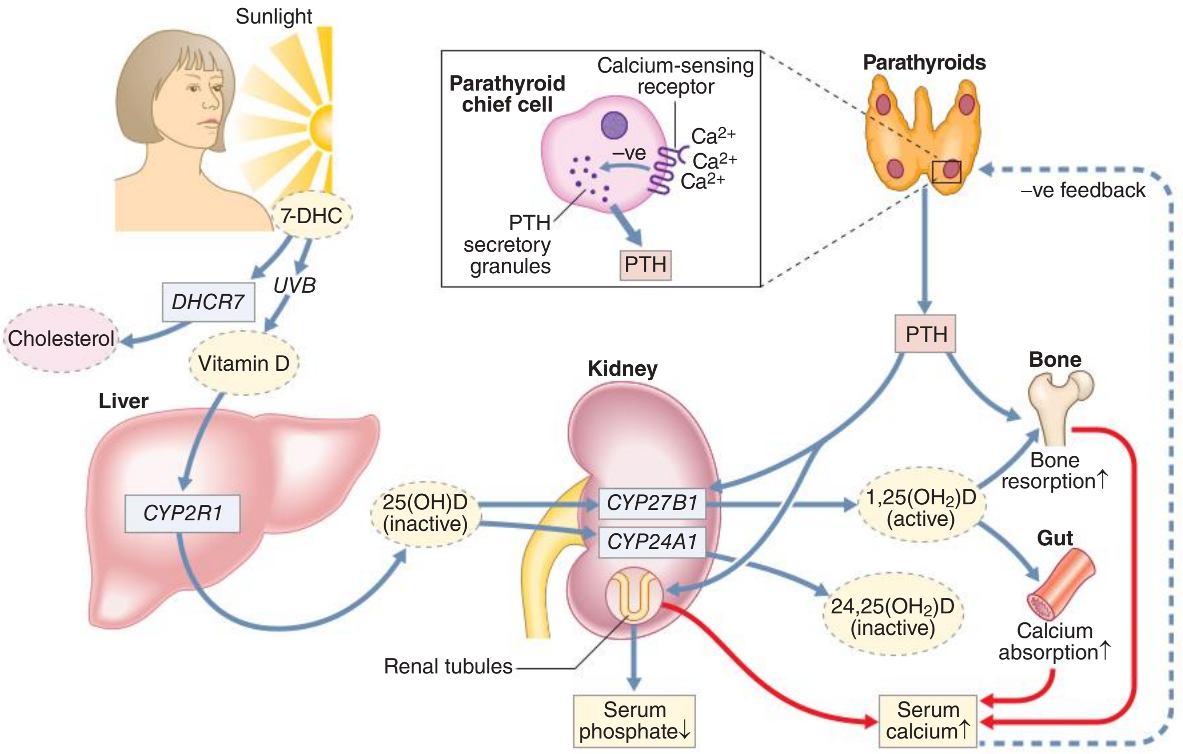

Fig. 25.60 Vitamin D metabolism. Vitamin D is produced in the skin from 7-dehydrocholesterol (7-DHC) by ultraviolet B (UVB) light. The 7-dehydrocholesterol reductase enzyme, which is encoded by the *DHCR7* gene, opposes the effect of UVB by converting 7-DHC to cholesterol. The vitamin D then undergoes hydroxylation steps in the liver and kidney to form the active metabolite 1,25(OH)$_2$D, which regulates calcium homeostasis by stimulating calcium absorption from the diet and bone resorption. See text for details. (PTH = parathyroid hormone)

Clinical features

Low circulating levels of vitamin D do not cause symptoms unless the vitamin D deficiency is severe, so the diagnosis of vitamin D deficiency is primarily made as the result of biochemical testing. A wide range of diseases, including most types of cancer, diabetes, multiple sclerosis and chronic inflammatory diseases have been associated with vitamin D deficiency. Current evidence suggests that these are not causal associations, but explained by confounding whereby people who are unwell have reduced sunlight exposure and poor diet. If vitamin D deficiency is prolonged and severe, then osteomalacia and rickets may eventually occur, as discussed below.

Investigations

The diagnosis can be made by measurement of serum 25(OH)D. In patients with low 25(OH)D, measurements of PTH, serum calcium, phosphate and ALP should also be considered. Low levels of 25(OH)D in the absence of other abnormalities is unlikely to be of any clinical significance and in many cases is likely to be due to low levels of vitamin D-binding protein, the levels of which are genetically determined. If low 25(OH)D levels are combined with raised levels of PTH, this is of more significance since it indicates secondary hyperparathyroidism, which if untreated and prolonged, may impair bone health and eventually lead to osteomalacia or rickets.

Management

Vitamin D supplements should be considered in patients who have low 25(OH)D levels, particularly when PTH is elevated. In most young adults, greater exposure to UV light and cholecalciferol in a dose of 800 IU daily should be sufficient to correct the deficiency. Short courses of high-strength vitamin D can also be used, such as 20 000–25 000 IU once weekly for 4–6 weeks. The benefit of treating low 25(OH)D values in the absence of other abnormalities of calcium biochemistry is uncertain. There is some evidence that response to bisphosphonate treatment of osteoporosis is impaired in patients with vitamin D deficiency and this is an indication for supplements. Similarly, patients who are receiving intravenous bisphosphonates and denosumab for osteoporosis should have vitamin D deficiency corrected by supplementation to reduce the risk of hypocalcaemia.

Osteomalacia and rickets

Severe and prolonged vitamin D deficiency can result in the occurrence of osteomalacia in adults and rickets in children. Improvements in nutrition mean that these are now relatively uncommon conditions in high-income countries, but they remain prevalent in older housebound individuals, who may have a poor diet and limited sunlight exposure, in women who wear facial coverings such as the niqab or burka, and in people with malabsorption.

Pathogenesis

Osteomalacia and rickets occur as the result of chronic secondary hyperparathyroidism, which invariably accompanies severe and long-standing vitamin D deficiency. The sustained elevation in PTH levels maintains normal levels of serum calcium by increasing bone resorption, which eventually causes progressive demineralisation of the skeleton. Phosphate released during the process of bone resorption is lost through increased renal excretion, resulting in hypophosphataemia. The raised levels of PTH stimulate osteoblast activity and cause new bone formation, but the matrix is not mineralised properly because of deficiency of calcium and phosphate. The under-mineralised bone is soft, mechanically weak and subject to fractures, particularly stress fractures. Normal levels of serum calcium tend to be maintained until a very advanced stage, when hypocalcaemia may occur.

Clinical features

Vitamin D deficiency in children causes delayed development, muscle hypotonia, craniotabes (small unossified areas in membranous bones of the skull that yield to finger pressure with a cracking feeling), bossing of the frontal and parietal bones and delayed anterior fontanelle closure, enlargement of epiphyses at the lower end of the radius and swelling of the rib costochondral junctions ('rickety rosary'). Osteomalacia in adults can present with fractures and low BMD, mimicking osteoporosis. Other symptoms include bone pain and general malaise. Proximal muscle weakness is prominent, and the patient may walk with a waddling gait and struggle to climb stairs or stand up from a chair. There may be bone and muscle tenderness on pressure, and focal bone pain can be due to fissure fractures of the ribs and pelvis.

Investigations

The diagnosis can usually be made by measurement of serum 25(OH)D, PTH, calcium, phosphate and ALP. Typically, serum ALP levels are raised, 25(OH)D levels are undetectable and PTH is markedly elevated. Serum phosphate levels tend to be low, but serum calcium is usually normal, unless the disease is advanced. X-rays often show osteopenia or vertebral crush fractures and, with more advanced disease, focal radiolucent areas (pseudofractures or Looser zones) may be seen in ribs, pelvis and long bones (Fig. 25.61). In children, there is thickening and widening of the epiphyseal plate. A radionuclide bone scan may show multiple hot spots in the ribs and pelvis at the site of fractures and the appearance may be mistaken for metastases. Where there is doubt, the diagnosis can be confirmed by bone biopsy, which shows the pathognomonic increased thickness and extent of osteoid seams (see Fig. 25.61).

Management

Osteomalacia and rickets respond promptly to treatment with vitamin D. A wide variety of doses can be used. Treatment with between 10 000 and 25 000 IU daily for 2–4 weeks is associated with rapid clinical improvement, an elevation in serum 25(OH)D and a reduction in PTH. Serum ALP levels sometimes rise initially as mineralisation of bone increases, but eventually fall to within the reference range as the bone disease heals. Subsequently, the dose of vitamin D can usually be reduced to a maintenance level of 800–1600 IU daily (10–20 μg), except in patients with malabsorption, who may require higher maintenance doses.

Vitamin D-resistant rickets

This is a genetically determined condition that presents in childhood with rickets that is resistant to therapy with vitamin D in standard dosages.

Pathogenesis

Type I vitamin D-resistant rickets (VDRR) is caused by loss-of-function pathogenic variants in the 25(OH)D-1α-hydroxylase (*CYP27B1*) enzyme, which converts 25(OH)D to the active metabolite 1,25(OH)$_2$D$_3$. Type II VDRR is caused by loss-of-function pathogenic variants in the vitamin D receptor, which impair its ability to activate gene transcription. Both are recessive disorders and consanguinity is common.

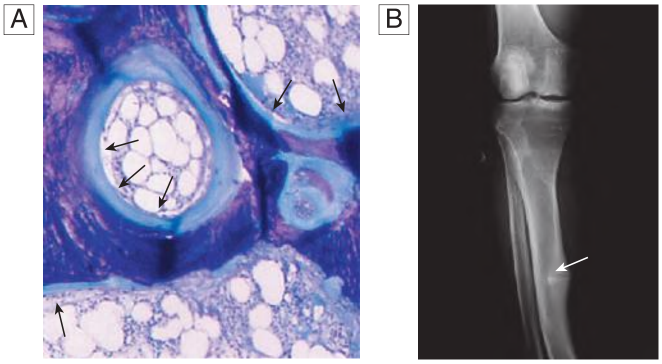

Fig. 25.61 Osteomalacia. **A** Photomicrograph of a toluidine blue–stained bone biopsy from a patient with osteomalacia showing thickened osteoid seams, stained light blue (arrows), covering most of the bone surface (left). Calcified bone is stained purple. **B** X-ray of a patient with osteomalacia showing a stress fracture of the tibia (arrow).

Clinical features

These are as described above for infantile rickets. The diagnosis is usually first suspected when the patient fails to respond to vitamin D supplementation.

Investigations

The biochemical features of type I VDRR are like those of ordinary vitamin D deficiency, except that levels of 25(OH)D are normal, but 1,25(OH)$_2$D is low. In type II VDRR, 25(OH)D is normal, but PTH and 1,25(OH)$_2$D$_3$ values are raised. The diagnosis can be confirmed by genetic testing.

Management

Type I VDRR responds fully to treatment with the active vitamin D metabolites 1α-hydroxy-vitamin D (1–2 μg daily, orally) or 1,25-dihydroxy-vitamin D (0.25–1.5 μg daily, orally). Calcium supplements are not necessary unless there is dietary deficiency. Type II VDRR sometimes responds partially to very high doses of active vitamin D metabolites, which can activate the mutant receptor, although additional calcium and phosphate supplements are also necessary.

Hereditary hypophosphataemic rickets

This group of disorders are caused by inherited defects in renal tubular phosphate reabsorption. The most common is X-linked hypophosphataemic rickets (XLH), but autosomal dominant and autosomal recessive forms also occur (see Box 25.74).

Pathophysiology

Most forms of hereditary hypophosphataemic rickets are associated with raised circulating concentrations of the phosphate-regulating hormone fibroblast growth factor 23 (FGF23). This hormone is produced by osteocytes (see Fig. 25.2) and enters the circulation, where it is normally inactivated by proteolytic cleavage. Production of FGF23 by osteocytes is under tonic inhibition by DMP1 and PHEX. In XLH, the inhibitory effect on FGF23 production is lost due to pathogenic loss-of-function variants in *PHEX* and a similar situation occurs in autosomal recessive hypophosphataemic rickets (ARHR1) due to pathogenic loss-of-function variants in *DMP1*. In autosomal dominant hypophosphataemic rickets (ADHR), there are pathogenic variants in *FGF23*, which result in the protein being degraded, thereby causing accumulation of intact FGF23 hormone in the circulation. In all three diseases, the elevation in FGF23 results in osteomalacia and rickets by causing phosphaturia by down-regulation of sodium-dependent phosphate transporters in the renal tubules, and by inhibiting conversion of 25(OH)D to 1,25(OH)$_2$D by the kidney, which in turn causes reduced calcium and phosphate absorption from the gut.

Clinical features

The presentation is with symptoms and signs of rickets during childhood that do not respond to vitamin D supplementation. In adults, hypophosphataemic rickets may be accompanied by dental abscesses, and by bone and joint pain due to the development of an enthesopathy or stress fractures.

Investigations

The diagnosis can be confirmed by genetic testing. Routine biochemistry shows a low serum phosphate and a reduction in tubular reabsorption of phosphate. Serum concentrations of FGF23 are markedly elevated. Serum levels of 25(OH)D are variable and PTH is normal or elevated.

Management

The aim of treatment is to ameliorate symptoms, restore normal growth and maintain serum phosphate levels within the reference range. Burosumab, a neutralising antibody to FGF23, is now the treatment of choice for XLH in both children and adults as it reverses the metabolic abnormalities that are typical of the disorder. If for any reason burosumab cannot be given, XLH can be treated with phosphate supplements (1–4 g daily) and alfacalcidol (1–2 μg daily) or calcitriol (0.5–1.5 μg daily), with the aim of promoting intestinal calcium and phosphate absorption. Levels of calcium and phosphate, as well as renal function, should be monitored regularly during treatment and renal ultrasound examination is recommended periodically to check for evidence of nephrocalcinosis. The therapeutic goal is to maintain serum phosphate concentrations within the normal range, but to avoid hypercalcaemia.

Tumour-induced osteomalacia

This is a rare syndrome caused by over-production of FGF23 by mesenchymal tumours. The presentation is with severe osteomalacia and hypophosphataemia in an adult patient with no obvious predisposing risk factor for vitamin D deficiency. Biochemical findings are as described for hereditary hypophosphataemic rickets. The underlying tumour can be difficult to find and multiple modality imaging with whole-body MRI, CT and somatostatin or gallium-68 (^{68}Ga)-DOTATATE PET-CT scintigraphy is often needed. Options for medical management include phosphate supplements and active vitamin D metabolites or burosumab, but the treatment of choice is surgical resection of the primary tumour, which is curative.

Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder caused by loss-of-function pathogenic variants in the *TNALP* gene, which results in accumulation of pyrophosphate and inhibition of bone mineralisation. The typical presentation is with severe intractable rickets during infancy, sometimes in association with seizures. Investigations show low or undetectable levels of serum ALP, but normal levels of calcium, phosphate, PTH and vitamin D metabolites. Urine excretion of pyridoxal 5′ phosphate and phosphoethanolamine (substrates for ALP) is increased. In severely affected patients, remarkable therapeutic responses have been obtained with recombinant ALP therapy (asfotase alfa), which is curative. Heterozygous carriers of these variants in *TNALP* are often asymptomatic and picked up as the result of a low ALP. There is some evidence that they may be at increased risk of osteoporosis. If present, osteoporosis can be treated with standard therapy. Enzyme replacement is seldom used in heterozygotes due to the high cost but can be considered on a case-by-case basis.

Other causes of osteomalacia

These are summarised in Box 25.74. Osteomalacia may occur as a component of renal osteodystrophy in patients with chronic kidney disease. The mechanism is reduced conversion of 25(OH)D into the active metabolite 1,25(OH)$_2$D by the failing kidney. Aluminium intoxication is now rare due to reduced use of aluminium-containing phosphate binders and removal of aluminium from the water supplies used in dialysis. If aluminium intoxication is suspected, the diagnosis can be confirmed by demonstration of aluminium at the calcification front in a bone biopsy. Osteomalacia due to bisphosphonates has mostly been described in patients with Paget disease who are receiving etidronate and high-dose pamidronate. It is usually asymptomatic, and healing occurs when treatment is stopped. Excessive fluoride intake causes osteomalacia due to direct inhibition of mineralisation and is common in parts of the world where there is a high fluoride content in drinking water. The condition reverses when fluoride intake is reduced. Also, repeated IV iron preparations have been linked to causing (FGF23-mediated renal phosphate-wasting) hypophosphataemic osteomalacia. Data suggests ferric carboxymaltose is most commonly implicated. The mechanism is still to be determined. The condition resolves on cessation of the relevant IV iron.

Paget disease of bone

Paget disease of bone (PDB) is characterised by focal areas of increased and disorganised bone remodelling involving one or more skeletal sites. The disease is common in the UK, affecting about 0.2% of those aged above 60. It is less common in other countries in Europe and is rare in Asia. The prevalence doubles each decade from the age of 50 onwards and affects up to 7% of the UK population by the age of 85.

Pathophysiology

The primary abnormality is increased osteoclastic bone resorption, accompanied by marrow fibrosis, increased vascularity of bone and increased, but disorganised, bone formation. Osteoclasts in PDB are greater in number and unusually large, containing characteristic nuclear inclusion bodies. Genetic factors are important and pathogenic variants in the *SQSTM1* gene are a common cause of classical PDB. The presence of nuclear inclusion bodies in osteoclasts has fuelled speculation that PDB might be caused by a slow virus infection, but this remains unproven, and recent evidence suggests they may be aggregates of undegraded proteins. Biomechanical factors may influence which bones are affected, as PDB often starts at sites of muscle insertions into bone and, in some cases, localises to bones or limbs that have been subjected to repetitive trauma or overuse. Involvement of subchondral bone can compromise the joint and predispose to OA. The prevalence of PDB has fallen in many countries over recent decades, indicating that environmental factors play a role, but their identity remains unclear.

Clinical features

The axial skeleton is predominantly affected, and commonly affected sites are the pelvis, femur, tibia, lumbar spine, skull and scapula. The most common presentation is with musculoskeletal pain. This can either be due to increased metabolic activity of the disease, deformity or stress fractures. More commonly it is due to a coexisting problem, particularly osteoarthritis. Paget disease can occasionally present with bone deformity, deafness and pathological fractures. Sometimes no symptoms are present, and in about 20% the diagnosis is made by imaging or finding a raised ALP on a blood test performed for another reason. Clinical signs include bone deformity and expansion, and increased warmth over an affected bone. Neurological problems, such as deafness, cranial nerve defects, nerve root pain, spinal cord compression and spinal stenosis, may occur due to enlargement of affected bones and encroachment on the spinal cord and nerve foramina. Surprisingly, deafness is seldom due to compression of the auditory nerve, but instead is conductive in nature due to osteosclerosis of the temporal bone. The increased vascularity of Pagetic bone can very rarely precipitate high-output cardiac failure in older patients with limited cardiac reserve. Osteosarcoma is an unusual but serious complication that presents with increasing pain and swelling of an affected site.

Investigations

The characteristic features are an isolated elevation in ALP and bone expansion on X-rays, with alternating areas of radiolucency and osteosclerosis (Fig. 25.62). Levels of ALP can be normal if only a single bone is affected. The best way of identifying affected sites is a radionuclide bone scan, which shows increased uptake in affected bones (see Fig. 25.62). If the bone scan is positive, X-rays should be taken to confirm the diagnosis. Bone biopsy is not usually required but may help to exclude osteosclerotic metastases in cases of diagnostic uncertainty.

Management

The main indication for treatment with inhibitors of bone resorption is bone pain, localised to an affected site, which is thought to be due to increased metabolic activity. Patients should be carefully assessed to determine the cause of the pain since it can be difficult to differentiate the pain caused by increased metabolic activity of PDB from that caused by complications such as bone deformity, nerve compression symptoms and OA. Various agents can be used (Box 25.75), but zoledronic acid is considered the treatment of choice since it is highly effective at

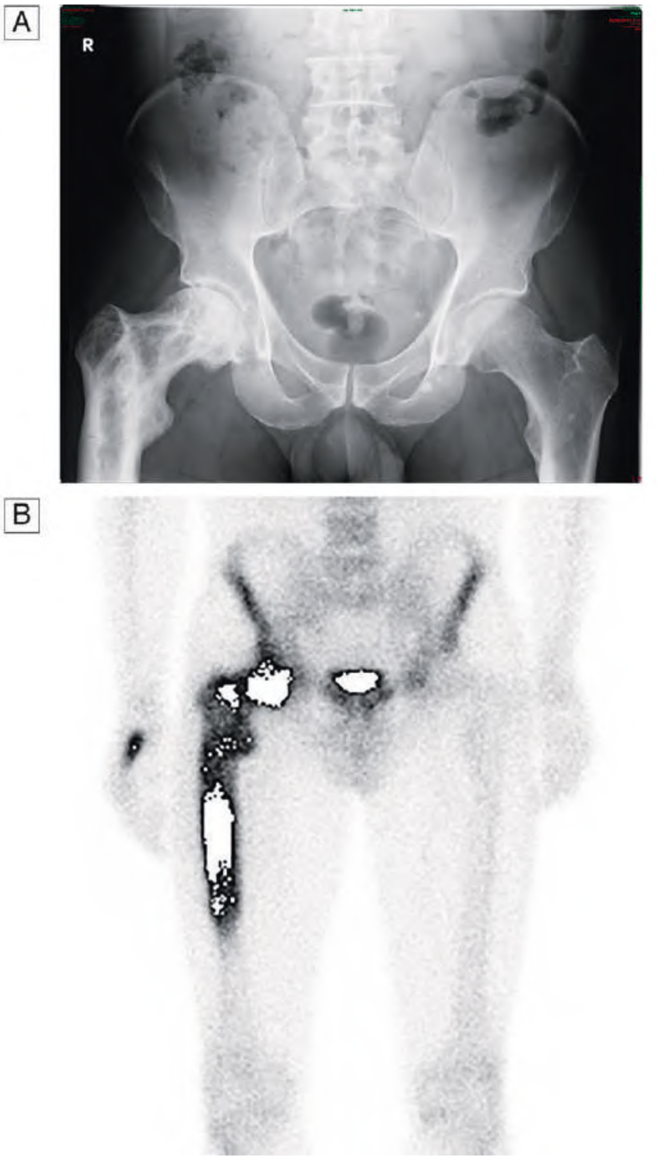

Fig. 25.62 Paget disease of bone. A X-ray showing Paget disease of the upper right femur illustrating osteolytic and osteosclerotic bone, a coarsened trabecular pattern and bone expansion with a stress fracture (arrow) visible on the lateral aspect of the femur. B Bone scintigraphy from the same patient showing intense tracer uptake in the affected bone.

suppressing elevated bone turnover in PDB and is most likely to give a favourable pain response. Intravenous pamidronate and oral risedronate can also be effective. Calcitonin may also help symptoms but is seldom used unless there is a contraindication to bisphosphonate therapy. If there is doubt about whether the pain is due to PDB, it can be worthwhile giving a therapeutic trial of bisphosphonate to determine whether the symptoms improve. A positive response usually indicates that the pain was due to increased metabolic activity. Repeated courses of bisphosphonates can be given if symptoms recur. Recent studies have shown that prophylactic zoledronic acid can reverse or arrest early PDB in asymptomatic carriers of pathogenic *SQSTM1* variants.

25.75 Medical management of Paget disease

Drug	Route of administration	Dose
Risedronate	Oral	30 mg daily for 2 months
Pamidronate	IV	1–3 × 60 mg infusions
Zoledronic acid	IV	1 × 5 mg infusion
Calcitonin	SC	100–200 IU 3 times weekly for 2–3 months

(IV = intravenous; SC = subcutaneous)

Other bone diseases

Complex regional pain syndrome type 1

Complex regional pain syndrome (CRPS) type 1 is characterised by gradual onset of pain, swelling and local tenderness, usually affecting a limb extremity. It may be triggered by fracture but can also occur in association with soft tissue injury, pregnancy and intercurrent illness or can develop spontaneously. The cause is unknown, but abnormalities of the sympathetic nervous system are thought to play a pathogenic role. The affected limb is swollen and tender, and there may be evidence of regional autonomic dysfunction with abnormal sweating and changes in skin colour and temperature. The diagnosis is primarily clinical, based on the features shown in Box 25.76. Support for the diagnosis can be obtained with MRI, which shows bone marrow oedema, or radionuclide bone scan, which shows a local increase in tracer uptake. X-rays typically show localised patchy osteoporosis. Haematology, biochemistry and immunology are normal.

The aims of treatment are to control pain and encourage mobilisation. Analgesics, NSAIDs, antineuropathic agents, calcitonin, glucocorticoids, β-adrenoceptor antagonists (β-blockers), sympathectomy and bisphosphonates have all been tried with variable efficacy. Pain can resolve in some patients with time, but many have persistent symptoms and fail to regain normal function.

25.76 The Budapest Criteria for diagnosis of chronic regional pain syndrome type 1

Category	Symptom or sign
Sensory	• Allodynia to: ◦ Temperature ◦ Light touch ◦ Deep somatic pressure ◦ Movement • Hyperalgesia to pin-prick
Vasomotor	• Temperature asymmetry • Skin colour change and/or asymmetry
Sudomotor	• Oedema • Sweating change and/or asymmetry
Motor/trophic	• Reduced range of motion • Motor dysfunction: ◦ Weakness ◦ Tremor ◦ Dystonia • Trophic changes: ◦ Hair ◦ Nails ◦ Skin

Type 1 CRPS: without evidence of major nerve damage.
Type 2 CRPS: evidence of major nerve damage.
For a positive diagnosis, the patient should report at least one symptom in at least three out of the four categories, and at least one sign should be observed in two out of the four categories. Other causes that might explain the signs and symptoms should be excluded.

Osteonecrosis

Osteonecrosis is the term used to describe death of bone due to impairment of its blood supply. Frequently affected sites are the femoral head, humeral head, navicular and scaphoid. In some cases, the condition occurs as the result of direct trauma that interrupts the blood supply to the affected bone. This is the reason for osteonecrosis of the femoral head following fractures of the femoral neck and in patients with thrombophilia, antiphospholipid syndrome, Gaucher disease and haemoglobinopathies, such as sickle-cell disorder. Other important predisposing factors include high-dose glucocorticoid treatment, alcohol excess, SLE, HIV and radiotherapy, but in many of these conditions pathophysiology is poorly understood. The presentation is with pain localised to the affected site, which is exacerbated by weight-bearing. The diagnosis can be confirmed by MRI, which shows evidence of subchondral necrotic bone and bone marrow oedema. X-rays are normal in the early stages, but later may show evidence of osteosclerosis and deformity of the affected bone. There is no specific treatment. Management should focus on controlling pain and encouraging mobilisation. Symptoms often improve spontaneously with time, but joint replacement may be required in patients who have persisting pain in association with significant structural damage to the affected joint.

Scheuermann osteochondritis

This disorder predominantly affects adolescent boys, who develop a dorsal kyphosis in association with irregular radiographic ossification of the vertebral end plates. It has a strong genetic component and may sometimes be inherited in an autosomal dominant manner. Most patients are asymptomatic, but back pain aggravated by exercise and relieved by rest may occur. Excessive exercise and heavy manual labour before epiphyseal fusion has occurred may aggravate symptoms. Management consists of advice to avoid excessive activity and provision of protective postural exercises. Rarely, corrective surgery may be required if there is severe deformity. Scheuermann disease can sometimes present for the first time in adulthood, when it can be confused with osteoporotic vertebral fractures. It can be differentiated from osteoporosis by the characteristic X-ray changes, which show mild wedge deformity of 3–4 adjacent vertebrae, irregularity of the vertebral end plates, and normal BMD on DXA examination.

Fibrous dysplasia

This is an acquired systemic disorder that mainly affects the skeleton and is caused by somatic gain-of-function pathogenic variants in the *GNAS1* gene. The characteristic presentation is with bone pain and pathological fractures. Associated features include endocrine dysfunction, especially precocious puberty, and café-au-lait skin pigmentation (McCune–Albright syndrome). The diagnosis can usually be made by imaging, which shows focal, predominantly osteolytic lesions with bone expansion on X-rays (Fig. 25.63), and focal increased uptake on bone scan. The condition may cause a single (monostotic) or multiple (polyostotic) lesions. The condition can superficially resemble Paget disease of bone, but the earlier age of onset and pattern of involvement are usually distinctive. Very rarely, malignant change can occur and should be suspected if there is a sudden increase in pain and swelling. Management is symptomatic. Intravenous bisphosphonates are often used in an attempt to control pain, but the evidence base for their efficacy is weak. Orthopaedic surgery may be required for treatment of fracture and deformity or to prevent a pathological fracture in a weight-bearing bone. Endocrine manifestations, such as precocious puberty, may require specific treatment.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is the name given to a group of disorders characterised by severe osteoporosis and multiple fractures in infancy and childhood. In about 80% of cases the disease is caused by pathogenic loss-of-function variants in the *COL1A1* and *COL1A2* genes, which encode proteins that make type I collagen. These result in reduced collagen production (in mild OI) or in formation of abnormal collagen chains that are rapidly degraded (in severe OI). Pathogenic variants in several other genes have been described that can cause OI, some of which affect post-translational modification of collagen and others that affect bone formation. Many patients have no family history. Some of these have new variants whereas others may have recessive forms of the disease. The Sillence classification is commonly used to grade severity in people with pathogenic *COL1A1* or *COL1A2* variants. This varies from neonatal lethal OI (type II), through very severe OI with multiple fractures in infancy and childhood (types III and IV), to mild (type I), in which affected patients typically have blue sclerae. The typical presentation of OI is with low trauma fractures during infancy, but the high fracture rate persists throughout life. However, OI is a systemic disease with effects on the cardiopulmonary and gastrointestinal system, soft tissues, tendons, muscle, and joints, hearing, eyesight, and dental health. The diagnosis is often made clinically but increasingly is confirmed by genetic testing. The disease can be mistaken for non-accidental injury in childhood and for osteoporosis in adulthood; in such cases, genetic testing is of particular value. Treatment is multidisciplinary, involving surgical reduction and fixation of fractures and correction of limb deformities, with physiotherapy and occupational therapy for rehabilitation of patients with bone deformity. Bisphosphonates are widely used in the treatment of children and adolescents with OI, especially intravenous pamidronate and zoledronic acid, but there is limited evidence for efficacy in fracture prevention. Adults are also prescribed bisphosphonates but with no evidence for efficacy in fracture prevention. A recent trial of TPTD followed by ZA similarly showed no anti-fracture efficacy in OI, illustrating the importance of reduced bone quality rather than reduced bone density in the pathogenesis of fractures.

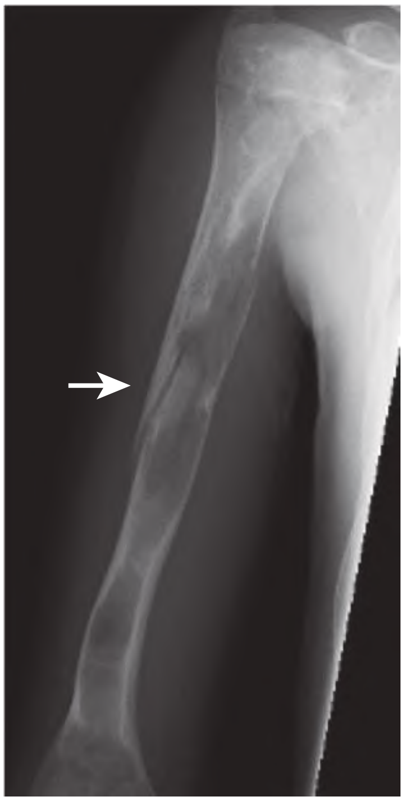

Fig. 25.63 Fibrous dysplasia. X-ray of the right humerus in a patient with polyostotic fibrous dysplasia showing multiple expansile osteolytic lesions and a pathological fracture in the humeral mid-shaft (arrow).

Osteopetrosis

Osteopetrosis is the collective name given to a rare group of inherited diseases caused by failure of osteoclast function. Presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers–Schönberg disease) shows autosomal dominant inheritance and presents with bone pain, cranial nerve palsies, osteomyelitis, OA or fracture; it is sometimes detected as an incidental radiographic finding. The pathogenic loss-of-function variants responsible for 'osteoclast-poor' osteopetrosis affect *TNFRSF11A* or *TNFRSF11*, which encode RANK and RANKL, respectively. Both proteins are critical for osteoclast differentiation. Pathogenic variants in genes involved in bone resorption cause 'osteoclast-rich' osteopetrosis. These include variants in *TCIRG1*, which encodes a component of the osteoclast proton pump, and variants in *CLCN7*, which encodes the osteoclast chloride pump. The most effective treatment is bone marrow transplantation that can provide a source of osteoclasts that resorb bone normally, but this is not effective in patients with pathogenic variants in *RANKL*. Medical management has limited efficacy, but IFN-γ treatment may improve blood counts and reduce the frequency of infections.

Fibrodysplasia ossificans progressiva

Fibrodysplasia ossificans progressiva (FOP) is a rare inherited disorder caused by heterozygous gain-of-function pathogenic variants in *ACVR1*, which encodes the activin A receptor type 1, a bone morphogenetic protein (BMP) type 1 receptor. It is characterised by widespread foci of heterotopic ossification (HO) affecting muscle and soft tissues, which cause severe pain, deformity, disability and early mortality. Intermittent inflammatory flare ups triggered by injury, injections or surgery can occur. Corticosteroids (prednisolone 40 mg daily) are indicated to treat flare ups, and many patients are on low-dose prednisolone long term. Until recently there had been no disease-modifying therapy. Palovarotene, a retinoid receptor agonist, has recently been approved by the FDA to prevent new bone lesions in FOP but was rejected by the European Medicines Agency (EMA) for this indication due to concerns about efficacy. Garetosmab, an antibody to activin A, has shown promising results in blocking the development of new lesions and reducing the number of flare ups.

Sclerosing bone dysplasias

These are rare diseases characterised by osteosclerosis and increased bone formation. Van Buchem disease and sclerosteosis are recessive disorders caused by pathogenic loss-of-function variants in the *SOST* gene, which encodes sclerostin, a protein which suppresses bone formation and increases bone resorption (see Fig. 25.2). The resulting lack of functional sclerostin increases bone formation and reduces bone resorption causing bone overgrowth, with enlargement of the cranium and jaw, tall stature and cranial nerve palsies. There is no effective treatment. High bone mass syndrome is a benign disorder caused by pathogenic variants in *LRP4* or *LRP5*. It is characterised by unusually high bone density. The variants render the LRP receptors resistant to the inhibitory effects of sclerostin. Most patients are asymptomatic, but bone overgrowth in the palate (torus palatinus) and enlargement of the mandible can occur in later life. Treatment is not usually required. Camurati–Engelmann disease is an autosomal dominant condition caused by gain-of-function pathogenic variants in *TGFB1*. It presents with bone pain, muscle weakness and osteosclerosis mainly affecting the diaphysis of long bones. Glucocorticoids can help the bone pain, although usually analgesics are also required.

Achondroplasia

Achondroplasia is a rare genetic disorder characterised by short stature, limb shortening, foramen magnum stenosis and hearing impairment caused by gain-of-function pathogenic variants in *FGFR3*, which encodes the fibroblast growth factor receptor 3. It is inherited in an autosomal dominant fashion. The diagnosis can usually be made clinically and confirmed by genetic testing. Kyphoscoliosis and spinal stenosis are common complications in adulthood. Vosoritide, a C-type natriuretic peptide analogue, has been found to increase linear growth in children with achondroplasia, but the effect on health-related quality of life in the long term remains to be determined. Surgical decompression of the foramen magnum and corrective orthopaedic surgery for limb deformity and kyphoscoliosis may be required.

Bone and joint tumours

Primary tumours of bones and joints are rare, have a peak incidence in childhood and adolescence, and can be benign or malignant (Box 25.77). Paget disease of bone accounts for most cases of osteosarcoma occurring above the age of 40.

Osteosarcoma

This is a rare tumour with an incidence of 0.6–0.85 per 100 000 population. It is the most common primary bone tumour. Most patients present under the age of 30, but osteosarcoma also occurs in old age in association with Paget disease. The presentation is with local pain and swelling. X-rays show expansion of the bone with a surrounding soft tissue mass, often containing islands of calcification. If the diagnosis is being considered, MRI or CT should be performed to determine the extent of tumour. Patients suspected of having osteosarcoma should be referred to a specialist oncology team for management. Treatment depends on histological type, but generally involves surgical removal of the tumour, followed by chemotherapy and radiotherapy. The prognosis is normally good in cases that present in childhood and adolescence, but poor in older patients.

Chondrosarcoma

This is the second most common primary bone tumour. Presentation is as described for osteosarcoma. The treatment of choice is surgical resection since chondrosarcomas are relatively resistant to chemotherapy and radiotherapy. The prognosis is good for low-grade tumours, but poor for anaplastic tumours.

Ewing sarcoma

This is the third most common sarcoma, which presents almost exclusively under the age of 40. Presentation is as described for osteosarcoma. Treatment is by local excision and surgical resection. The prognosis is excellent for patients who present before metastasis has occurred.

Metastatic bone disease

Metastatic bone disease may present in a variety of ways: with localised or generalised progressive bone pain, generalised regional pain, symptoms of spinal cord compression, or acute pain due to pathological fracture.

25.77 Primary tumours of the musculoskeletal system

Cell type	Benign	Malignant
Osteoblast	Osteoid osteoma	Osteosarcoma
Chondrocyte	Chondroma Osteochondroma	Chondrosarcoma
Fibroblast	Fibroma	Fibrosarcoma
Bone marrow cell	Eosinophilic granuloma	Ewing sarcoma
Endothelial cell	Haemangioma	Angiosarcoma
Osteoclast precursor	Giant cell tumour	Malignant giant cell tumour

Systemic features, such as weight loss and anorexia, and symptoms referable to the primary tumour are often present. The tumours that most commonly metastasise to bone are myeloma and those of bronchus, breast, prostate, kidney and thyroid. Management is discussed in Chapter 8.

Rheumatological involvement in other diseases

Many systemic diseases can affect the locomotor system, and many drugs may cause adverse musculoskeletal effects (Box 25.78). The most common examples are described here.

Malignant disease

Malignant disease can cause a variety of non-metastatic musculoskeletal problems (Box 25.79). One of the most striking is hypertrophic pulmonary osteoarthropathy (HPOA), characterised by clubbing and painful swelling of the limbs, periosteal new bone formation and arthralgia/arthritis. The most common causes are bronchial carcinoma and mesothelioma. Bone scintigraphy shows increased periosteal uptake before new bone is apparent on X-ray. The course follows that of the underlying malignancy, and HPOA resolves if malignancy is cured.

25.78 Drug-induced effects on the musculoskeletal system: common examples

Musculoskeletal problem	Principal drugs
Secondary gout	Thiazides, furosemide, alcohol
Osteoporosis	Glucocorticoids, heparin, glitazones, aromatase inhibitors, GnRH agonists
Osteomalacia	Anticonvulsants, etidronate and pamidronate (high-dose)
Osteonecrosis	Glucocorticoids, alcohol
Drug-induced lupus syndrome	Procainamide, hydralazine, isoniazid, chlorpromazine, minocycline, anti-TNF-α biologics
Arthralgias	Glucocorticoid withdrawal, glibenclamide, methyldopa, ciclosporin, isoniazid, barbiturates, bisphosphonates, aromatase inhibitors
Myalgia	Glucocorticoid withdrawal, L-tryptophan, fibrates, statins
Myopathy/myositis	Glucocorticoids, chloroquines, penicillamine, statins, zidovudine, colchicine, fibrates, alcohol
Arthritis	Immune checkpoint inhibitors
Vasculitis	Penicillins, cephalosporins, sulphonamides, thiazides, phenytoin, allopurinol

(GnRH = gonadotrophin-releasing hormone)

25.79 Rheumatological manifestations of malignancy

- Polyarthritis
- Dermatomyositis and polymyositis
- Hypophosphataemic osteomalacia
- Hypertrophic osteoarthropathy
- Vasculitis
- Autoimmune connective tissue disease
- Raynaud syndrome
- Polymyalgia rheumatica-like syndrome

Endocrine disease

Hypothyroidism may present with carpal tunnel syndrome or, rarely, with painful, symmetrical proximal myopathy and muscle hypertrophy. Both resolve with levothyroxine replacement. Primary hyperparathyroidism is associated with osteoporosis and also predisposes to CPPD disease and to calcific periarthritis, especially in patients with renal disease.

Diabetes mellitus commonly causes diabetic cheiroarthropathy, characterised by tightening of skin and periarticular structures, causing flexion deformities of the fingers that may be painful. Diabetic osteopathy presents as forefoot pain with radiographic progression from osteopenia to complete osteolysis of the phalanges and metatarsals. Diabetes also predisposes to osteoporosis, fragility fractures, adhesive capsulitis, Dupuytren contracture, osteomyelitis, septic arthritis and Charcot joints.

Acromegaly can be associated with mechanical back pain, with normal or excessive movement; carpal tunnel syndrome; Raynaud syndrome and an arthropathy (50%). This arthropathy mainly affects the large joints and has clinical similarities to OA, but with a normal or increased range of movement. X-rays may show widening of joint spaces, squaring of bone ends, generalised osteopenia and tufting of terminal phalanges. It does not improve with treatment of the acromegaly and is an important cause of reduced quality of life in affected individuals.

Haematological disease

Haemochromatosis is complicated by arthropathy in about 50% of cases. It typically presents between the ages of 40 and 50 and may predate other features of the disease. The small joints of the hands and wrists are typically affected, but the hips, shoulders and knees may also be involved. The X-ray changes resemble OA, but cysts are often multiple and prominent with little osteophyte formation. Involvement of the radiocarpal and MCP joints may occur, which is unusual in primary OA, and about 30% have CPPD. Treatment of the haemochromatosis does not influence the arthropathy, though methotrexate and colchicine are options for polyarticular chronic CPPD disease; otherwise, management is as described for OA. Haemophilia can be complicated by haemarthrosis, which, if recurrent, can result in the development of secondary OA. Sickle-cell disorder may be associated with bone pain, osteonecrosis and osteomyelitis. Thalassaemia may be complicated by bone deformity, especially affecting the craniofacial bones, and by osteoporosis.

Neurological disease

Neurological disease may result in rapidly destructive arthritis of joints, first described by Charcot in association with syphilis. The cause of Charcot arthropathy is incompletely understood but may involve repetitive trauma as the result of sensory loss and altered blood flow secondary to impaired sympathetic nervous system control. The main predisposing diseases and sites of involvement are:

- diabetic neuropathy (hindfoot)
- syringomyelia (shoulder, elbow, wrist)
- leprosy (hands, feet)
- tabes dorsalis (knees, spine).

The presentation is with subacute or chronic monoarthritis. Pain can occur, especially at the onset, but once the joint is severely deranged, pain is often minimal, and signs become disproportionately greater than symptoms. The joint is often grossly swollen, with effusion, crepitus, marked instability and deformity, but usually no increased warmth. X-rays show disorganisation of normal joint architecture and often multiple loose bodies (Fig. 25.64), and either no (atrophic) or gross (hypertrophic) new bone formation. Management principally involves orthoses and occasionally arthrodesis.

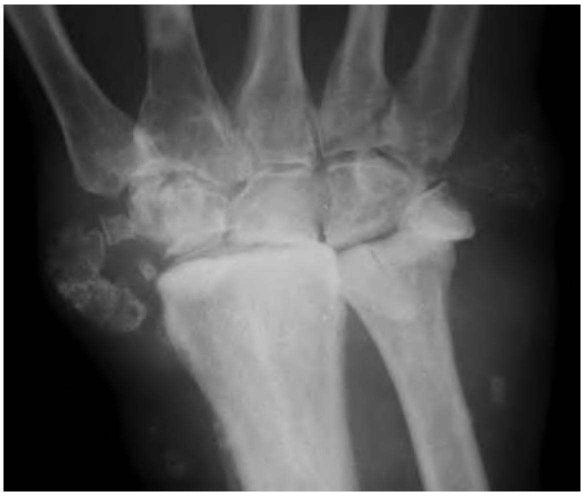

Fig. 25.64 **Wrist X-ray showing a neuropathic (Charcot) joint in a patient with syringomyelia.** Note the disorganised architecture with complete loss of the proximal carpal row, bony fragments and soft tissue swelling.

Miscellaneous conditions

Anterior tibial compartment syndrome

This is characterised by severe pain in the front of the lower leg, aggravated by exercise and relieved by rest. Symptoms result from fascial compression of the muscles in the anterior tibial compartment and may be associated with foot drop. Treatment is by surgical decompression.

Carpal tunnel syndrome

This is a common nerve entrapment syndrome caused by compression of the median nerve at the wrist. It presents with numbness, tingling and pain in a median nerve distribution.

Severe nerve compression can cause thumb weakness and thenar eminence muscle wasting. The differential diagnosis includes C6 radiculopathy. The most common non-mechanical, systemic causes are hypothyroidism, diabetes mellitus, rheumatoid arthritis, obesity and pregnancy (especially in the third trimester). In some patients, no underlying cause can be identified. Carpal tunnel syndrome often responds to treatment of the underlying condition, but other options include local glucocorticoid injections and surgical decompression.

Ulnar nerve neuropathy

The ulna nerve can be irritated or compressed at the elbow or wrist to cause symptoms and weakness in the hand. The distribution of sensory symptoms is in the lateral three fingers. Severe nerve compression can result in small hand (intrinsic) muscle wasting. Differential diagnosis includes C7–T1 radiculopathy and inclusion body myositis (IBM) (p. 1070). Causes include RA at the elbow and injuries/trauma at the wrist. Splinting, steroid injections at the site of nerve compression and surgery are therapy options.

Diffuse idiopathic skeletal hyperostosis

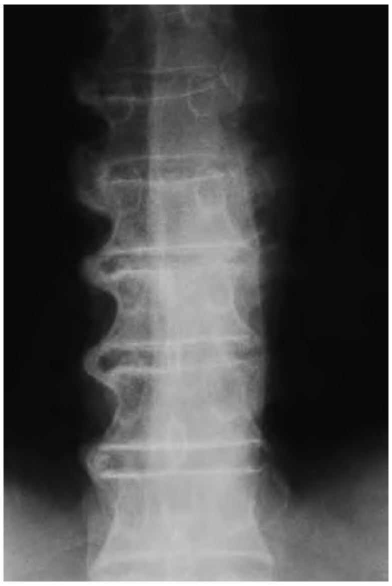

Fig. 25.65 **Diffuse idiopathic skeletal hyperostosis (DISH).** Anteroposterior X-ray of the thoracic spine showing right-sided, flowing new bone joining contiguous thoracic vertebrae. The disc spaces are preserved.

Diffuse idiopathic skeletal hyperostosis (DISH) is a common disorder, affecting 10% of men and 8% of women over the age of 65, but its prevalence increases further with age and is associated with obesity, hypertension and type 2 diabetes mellitus. It is characterised by syndesmophytes and florid new bone formation along the anterolateral aspect of contiguous vertebral bodies (Fig. 25.65). DISH is distinguished from lumbar spondylosis by the absence of disc space narrowing and marginal vertebral body sclerosis, and from ankylosing spondylitis by the absence of sacroiliitis or apophyseal joint fusion. It is usually an asymptomatic radiographic finding but can induce back pain through causing degenerative back disease, or pain at peripheral sites, such as the heel, in association with enthesophyte formation.

Dupuytren contracture

Dupuytren contracture is characterised by fibrosis and contracture of the superficial palmar fascia of the hands. The patient is unable to extend the fingers fully and there is puckering of the skin with palpable nodules. The ring and little fingers are usually the first and worst affected. Dupuytren contracture is usually painless but causes problems due to limitation of hand function and snagging of the curled fingers in pockets. It is age-related, usually bilateral and more common in men. There is a strong genetic component and it sometimes may be familial, with dominant inheritance. The condition can be associated with plantar fibromatosis, Peyronie disease, alcohol misuse and chronic vibration injury. It is very slowly progressive. Often no treatment is required, but it can be treated medically by local injections of collagenase or surgically by fasciotomy if symptoms are troublesome.

Hereditary diseases of connective tissue

Hereditary diseases of connective tissue (HDCT) are typically and prominently characterised by connective tissue laxity, a range of musculoskeletal, skin and internal organ dysfunction features and joint hypermobility. The main conditions are:

- Marfan syndrome
- Ehlers–Danlos syndromes (EDS)
- Osteogenesis imperfecta (p. 1086).

Marfan syndrome (1:5000) is caused by pathogenic variants in *FBN1*, which encodes fibrillin, an extracellular matrix protein. It is inherited in an autosomal dominant manner. Clinical features include long limbs, tall stature, scoliosis, high-arched palate, pes planus, joint hypermobility, skin striae and cutis laxa, aortic dilatation, aortic and mitral valve lesions, myopia and eye lens dislocation, pneumothoraces and myotonia. Loeys–Dietz syndrome is similar but is differentiated by the typical presence of aneurysms and arterial tortuosity.

Classical EDS can be caused by pathogenic loss-of-function variants in *COL5A1* or *COL5A2*, which encode the alpha 1 and alpha 2 chains of type 5 collagen, or loss-of-function variants in *COL1A1*, which encodes the alpha 1 chain of type 1 collagen. Classical EDS is inherited in an autosomal dominant manner. Clinical features include joint hypermobility combined with skin fragility and velvety or lax skin with extensive scarring. Vascular EDS (vEDS) is caused by pathogenic loss-of-function variants in *COL3A1*, which encodes type III collagen. It is inherited in an autosomal dominant manner. The most important complications are blood vessel dissection and rupture as well as hollow organ rupture, which are potentially fatal. Easy bruising and thin skin are common features. Generalised hypermobility is present in about one-third of patients. Treatment is with angiotensin receptor blockers or β-blockers to try to reduce the risk of vascular events. Hypermobile Ehlers–Danlos syndrome (hEDS), which is also known as EDS type 3, is used to describe a polygenic form of joint hypermobility. Typical features are recurrent dislocations, easy bruising, gastrointestinal symptoms, pelvic and bladder symptoms and postural orthostatic tachycardia syndrome (POTS), in which there is dizziness, hypotension and an increased heart rate on standing. Patients with hEDS who come to specialist care with widespread pains are often noted to have neurodiversity (autism, ADHD) with interoception and sensory processing risk factors. The Beighton score is useful to characterise the degree of joint hypermobility in all EDS types (Box 25.80) and is a key part of diagnosing hEDS (Box 25.81). In the EDS Society 2017 nosology, the term hypermobility spectrum disorder (HSD) can be assigned as a diagnosis where some features of hEDS are present but where there is no generalised joint hypermobility (see Box 25.81).

Pigmented villonodular synovitis

Pigmented villonodular synovitis is an uncommon proliferative disorder of synovium, which typically affects young adults. It is caused by a somatic chromosomal translocation in synovial cells that places the *CSF1* gene downstream of the *COL6A3* gene promoter. The result is local overproduction of M-CSF, which causes accumulation of macrophages in the joint. The presentation is with joint swelling, limitation of movement and local discomfort. The diagnosis can be confirmed by MRI or synovial biopsy. Treatment is by surgical or radiation synovectomy.

25.80 Beighton score to characterise joint hypermobility in Ehlers–Danlos syndromes

Clinical test	Score
Extend little finger $>90^{\circ}$	1 point each side
Bring thumb back parallel to/touching forearm	1 point each side
Extend elbow $>10^{\circ}$	1 point each side
Extend knee $>10^{\circ}$	1 point each side
Touch floor with flat of hands, legs straight	1 point
Note: Beighton scores can overestimate the presence of generalised hypermobility in children but underestimate it in older adults	

25.81 The 2017 international classification criteria for hypermobility Ehlers–Danlos syndrome (hEDS/type 3 EDS)

Criterion	Details
General joint hypermobility	Beighton score ≥ 6 for pre-pubertal children/adolescents, ≥ 5 for pubertal men and women up to age 50 years, and ≥ 4 for those >50 years of age (see Box 25.80)
Two features from:	Unusually soft or velvety skin, mild skin hyperextensibility, unexplained skin striae, bilateral piezogenic papules of the heel, recurrent or multiple abdominal hernias, atrophic skin scarring at ≥ 2 sites, otherwise unexplained pelvic floor, rectal, and/or uterine prolapse, dental crowding and high or narrow palate, arachnodactyly, arm span-to-height ≥ 1.05, mitral valve prolapse, aortic root dilatation
Exclusions	Other heritable and acquired connective tissue disorders including other types of EDS, Loeys–Dietz syndrome, Marfan syndrome, osteogenesis imperfecta and skeletal dysplasias
The clinical diagnosis of hEDS needs the simultaneous presence of all 3 criteria. Further details: doi.org/10.1002/ajmg.c.31552	

Scoliosis

Scoliosis is characterised by an abnormal lateral curvature of the spine of greater than 10 degrees. Scoliosis may be secondary to known disorders or idiopathic. In about 20% of cases, scoliosis is secondary to a neuromuscular disorder, such as muscular dystrophy, cerebral palsy or neurofibromatosis. It may also occur in association with hereditary connective tissue diseases, such as Marfan syndrome. Scoliosis may also develop in later life, usually because of structural changes in the spine from degenerative change. The term idiopathic scoliosis is used to describe the remaining cases where there is no obvious cause. In fact, there is strong evidence from twin studies that idiopathic scoliosis is genetically mediated, in keeping with the finding that it is evident during childhood or adolescence. It is often asymptomatic, but it can persist into adulthood and may become symptomatic, associated with evolving degenerative changes.

The diagnosis of scoliosis can be made clinically by physical examination and confirmed by X-ray. External bracing and/or surgical intervention may be considered in adolescents with severe deformities to correct deformity or prevent progression, but the evidence base is poor. In adulthood, treatment is symptomatic in nature with analgesics, NSAIDs or antineuropathic medications.

Spondylolysis and spondylolisthesis

Spondylolysis describes a break in the integrity of the vertebral neural arch. The principal cause is an acquired defect in the pars interarticularis due to a fracture, mainly seen in gymnasts, dancers and runners, in whom it is an important cause of back pain. Spondylolisthesis describes the condition in which a defect causes slippage of a vertebra on the one below. This may be congenital, post-traumatic or degenerative. Rarely, it can result from metastatic destruction of the posterior elements. Uncomplicated spondylolysis does not cause symptoms, but spondylolisthesis can lead to low back pain aggravated by standing and walking. Occasionally, symptoms of nerve root or spinal compression may occur. The diagnosis can be made on oblique X-rays of the lumbar spine, but MRI may be required if there is neurological involvement. Advice on posture and muscle-strengthening exercises is required in mild cases. Surgical fusion is indicated for severe and recurrent low back pain. Surgical decompression is mandatory prior to fusion in patients with significant lumbar stenosis or symptoms of cauda equina compression.

Chronic non-bacterial osteomyelitis and SAPHO syndrome

Chronic non-bacterial osteomyelitis (CNO) typically occurs in children, adolescents and young adults, and is characterised by pain, osteitis and osteosclerosis of affected bones. It may target a single bone or multiple bones. CNO can occur in the absence of other features or be part of the synovitis–acne–pustulosis–hyperostosis–osteitis (SAPHO) syndrome. These disorders often target the clavicles and bones of the anterior chest wall, but other bones may be affected, including the mandible, spine, pelvis and lower limb bones. CNO-SAPHO syndrome may be part of a spectrum of autoinflammatory bone disease that includes psoriatic arthritis. Other features of CNO-SAPHO include a pustular rash affecting the palms and soles of the feet, enthesitis, spondylodiscitis, sacroiliitis and synovitis of peripheral joints. The diagnosis can be confirmed with imaging: whole-body MRI is recommended in children, whereas in adults recommended options include MRI, NaF PET-CT or bone scintigraphy combined with CT scanning (SPECT). Regional imaging with X-rays and CT show osteosclerosis and hyperostosis in chronic cases. Various treatments have been used, including glucocorticoids, csDMARDs, bisphosphonates, anakinra, anti-TNF-α, and anti-IL-17, with most success arising from bDMARD use. The cause is unknown but has been suggested to be an autoinflammatory process triggered by a microorganism.

Multiple Choice Questions

25.1 Which of the following statements about classical synthetic disease-modifying antirheumatic drugs (csDMARDs) is true?

A. Leflunomide has a short half-life and clears from the body quickly when it is stopped
B. Sulfasalazine can stain contact lenses yellow
C. It is recommended that the genotype for polymorphisms in the thiopurine S-methyltransferase (TPMT) gene should be checked
D. Abnormalities of liver function tests and full blood count are common adverse effects of hydroxychloroquine therapy for rheumatoid arthritis
E. Methotrexate is safe to take throughout pregnancy

Answer: B.

A is *False* – leflunomide has a long half-life and takes many months to clear from the body when stopped. Excretion of leflunomide can be expedited by a short course of cholestyramine. B is *True* – urine can be yellow-stained also. C is *False* – TPMT is checked before azathioprine is prescribed. 1 in 300 people have a homozygous TPMT allele genotype which leads to very slow drug metabolism, which increases the risk of azathioprine toxicity markedly. D is *False* – abnormal LFT and FBC are not common adverse effects of hydroxychloroquine. E is *False* – methotrexate needs to be stopped 3 months before conception.

25.2 Which of the following statements about biologic disease-modifying antirheumatic drugs (bDMARDs/'biologics') is true?

A. Biologics are carcinogenic
B. Monoclonal antibodies to IL-17 are an effective treatment for rheumatoid arthritis
C. Like all anti-TNF-α therapies, etanercept can be used in axial spondyloarthritis patients to also control associated Crohn disease
D. All anti-TNF-α bDMARDs should be stopped in the third trimester of pregnancy since they cross the placenta and can cause immunosuppression in the neonate
E. In ANCA-positive vasculitis, a commonly used regimen to induce remission is rituximab 1 g by infusion 2 weeks apart coupled with reducing doses of glucocorticoids followed by further infusions of 500–1000 mg once every 6 months

Answer: E.

A is *False* – biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. B is *False* – anti IL-17 therapy is effective in psoriatic arthritis and axial spondyloarthritis but not in rheumatoid arthritis. C is *False* – anti-TNF-α monoclonal antibodies generally are effective in enteropathic arthritis, but etanercept should be avoided as it not effective in the treatment of inflammatory bowel disease. D is *False* – it is customary for most anti-TNF-α cDMARDs to be stopped because they cross the placenta, but an exception is certolizumab, which is a pegylated antibody that does not cross the placenta and can be used safely throughout pregnancy. E is *True* – various regimens of rituximab have been used in ANCA-positive vasculitis, but induction with rituximab 1000 mg 2 weeks apart followed by 500–1000 mg every 6 months is in common use.

25.3 Infections that affect the musculoskeletal system are not common but their effects can be severe. Which of the following statements about infections is true?

A. The mortality of septic arthritis is about 1%
B. Gonococcal septic arthritis is a symmetrical polyarthritis similar to rheumatoid arthritis
C. Diabetes is a particularly important risk factor for osteomyelitis, accounting for about 30% of cases
D. Where TB of a joint is suspected, fluid should be drawn and analysed by microscopy, culture and PCR
E. Tuberculosis may be accompanied by a reactive arthritis (Poncet disease), but unlike other forms of reactive arthritis, there is direct infection of the affected joints by tubercle bacilli

Answer: C.

A is *False* – overall, septic arthritis still has a mortality of about 10% despite advances in antimicrobial therapy. B is *False* – gonococcal infection can present with a migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. C is *True*. D is *False* – culture of synovial fluid is positive in between 20% and 40% of cases, but examination of synovial fluid or synovial tissue by PCR can yield the diagnosis more rapidly, with positive results in more than 95% of culture-positive cases and 50%–60% of culture-negative cases. E is *False* – in Poncet disease the affected joints are not directly infected.

25.4 Which of the following statements about osteoarthritis (OA) is true?

A. Across different ethnicities the prevalence of hip (10%) and knee (20%) OA has been found to be approximately the same
B. Generalised erosive osteoarthritis should be treated with csDMARDs
C. Unexplained early-onset OA requires additional investigation, as the condition can be caused by acromegaly, calcium pyrophosphate deposition disease, some skeletal dysplasias, Stickler syndrome and haemochromatosis amongst other conditions, for example
D. The thoracic spine facet joints and intervertebral disc–vertebral end plates are the sites in the spine most often affected by an OA process
E. Arthroplasty is an effective treatment for severe hip or knee OA. However, in over 50% of cases, joint replacements fail after 10 years

Answer: C.

A is *False* – the prevalence of OA rises progressively with age, and it has been estimated that 45% of all people develop knee OA and 25% hip OA at some point during life. Although some are asymptomatic, the lifetime risk of having a total hip or knee replacement for OA in someone aged 50 is about 11% for women and 8% for men in the UK. There are major ethnic differences in susceptibility: the prevalence of hip OA is lower in Africa, China, Japan and South Asia than in European countries, while that of knee OA is higher. B is *False* – in general, erosive OA does not respond to csDMARDs, though clinicians may in selected cases trial a csDMARD for a limited period of time. C is *True* – other conditions include X-linked hypophosphataemia and rare genetic conditions of cartilage and connective tissue matrix. D is *False* – the cervical and lumbar spine facet joints and intervertebral disc–vertebral end plates are the sites most often affected by an OA process, where the disease complex is referred to as cervical and lumbar spondylosis, respectively. E is *False* – over 95% of joint replacements completed for hip or knee OA continue to function well into the second decade after surgery, and most provide life-long, pain-free function.

25.5 In the investigation and management of ANCA-associated vasculitis (AAV), which of the following is true?

A. The most common presentation of granulomatosis with polyangiitis (GPA) is with skin rash and renal involvement

B. Imaging of the lungs is not necessary if the diagnosis of GPA has been made otherwise
C. Initial management of organ-threatening AAV is with mycophenolate or methotrexate plus glucocorticoids
D. In eosinophilic granulomatosis with polyangiitis (EGPA), once the condition is in remission, treatment can be stopped and patients can be reassured and discharged from follow-up care
E. Once remission of AAV is attained, rituximab is generally considered the most appropriate ongoing treatment to maintain remission

Answer: E.

A is *False* – the most common presentation of GPA is with epistaxis, nasal crusting and sinusitis, but haemoptysis and mucosal ulceration may also occur. Other head and neck features of GPA are deafness from inner ear involvement and proptosis from inflammation of the retro-orbital tissue. Skin rash and renal inflammatory involvement, though, are features of GPA. B is *False* – imaging of the upper airways, chest and nasal passages with MRI should always be considered, as airways involvement is common in GPA and defining the extent of GPA before treatment is started is advisable. C is *False* – initial management of organ-threatening AAV is with high-dose glucocorticoids and immunosuppressive therapy, such as pulse intravenous methylprednisolone 500–1000 mg daily for 3 days coupled with intravenous rituximab 1 g given twice 2 weeks apart. Oral cyclophosphamide up to 2 mg/kg/day for 3 months, or pulsed IV cyclophosphamide 15 mg/kg (IV) every 2–3 weeks for 6–10 doses, can be used as an alternative to rituximab. D is *False* – whatever the subtype, patients with AAV must be followed on a regular and long-term basis since the condition tends to relapse, monitoring urinalysis for blood and protein, plasma creatinine, FBC, ESR, CRP, lung function and PR3 or MPO antibody titres. E is *True* – azathioprine, MTX or MMF can be used as an alternative to rituximab to maintain remission but are less effective.

25.6 Which of the following statements is true about X-linked hereditary hypophosphataemic rickets (XLH)?
A. Women are more severely affected than men
B. The main underlying mechanism of hypophosphataemia is an elevation in circulating parathyroid hormone levels which promote urinary excretion of phosphate
C. Typical features on routine biochemical testing are an elevation in serum calcium and a reduction in serum phosphate with normal serum 25(OH)D concentrations
D. Circulating concentrations of FGF23 are significantly elevated
E. The condition is typically transmitted from affected fathers to their sons

Answer: D.

A is *False* – men are affected more severely than women as only one of the X-chromosomes carries a pathogenic variant in PHEX, the causal gene. B is *False* – although serum PTH can be elevated in XLH and high levels of PTH promote phosphate excretion, this is not the main cause of hypophosphataemia. C is *False* – although phosphate is low, serum calcium is normal or low in XLH. D is *True* – serum FGF23 is raised in XLH and this is the main cause of the hypophosphataemia, although the causal gene is PHEX, which is thought to regulate FGF23 production by mechanisms that are still poorly understood. E is *False* – the condition is X-linked, which means that father-to-son transmission is never observed. It is transmitted from mothers who are carriers of pathogenic variants in PHEX to their sons.

25.7 A 75-year-old woman presents with pain and stiffness in her shoulders of 8 weeks' duration. Examination is unremarkable and muscle power is normal. Investigations reveal a normal full blood count and normal routine biochemistry with CK 125 U/mL. The erythrocyte sedimentation rare is 55 mm/hr (normal <30) and CRP is 25 mg/L (normal <5). Immunology screen is negative. Testing for rheumatoid factor is positive, with a value of 8 units/mL (normal <5.1). What is the most likely diagnosis?
A. Rheumatoid arthritis
B. Fibromyalgia
C. Polymyositis
D. Polymyalgia rheumatica
E. Calcific tendinitis rotator cuff

Answer: D.

A is *False* – the clinical picture is not consistent with rheumatoid arthritis, which typically presents with swelling and stiffness of the small joints of the hands and feet. Although rheumatoid factor is slightly raised, this is almost certainly a false positive, as low concentrations of rheumatoid factor are common above the age of 70. B is *False* – fibromyalgia is associated with generalised pain and local tender spots. The symptoms are not localised to the shoulder girdle and inflammatory markers are normal in fibromyalgia. C is *False* – the predominant symptom in polymyositis is muscle weakness rather than pain, and CK is almost always raised. D is *True* – the clinical features of proximal muscle pain and stiffness affecting the shoulder girdle in a woman of this age in the absence of muscle weakness is typical of polymyalgia rheumatica. E is *False* – although calcific tendinitis can cause shoulder pain, it is not associated with an increase in inflammatory markers like CRP and ESR.

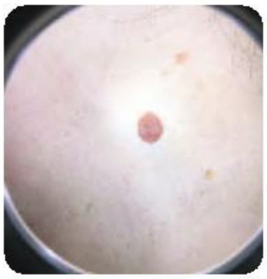
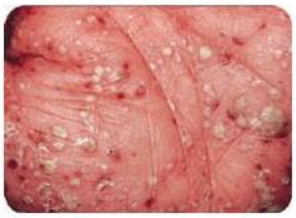
Clinical examination in skin disease

8 Detailed morphology of individual lesions

Use a magnifying lens in good lighting to assist
Use correct terminology (see definitions throughout text)



Magnifying lens image of benign naevus



Palmoplantar pustulosis

7 Overall description of individual lesions

Discrete, grouped, confluent, reticulate (lace-like), linear

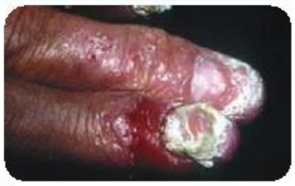
6 Morphology of rash

Monomorphic or polymorphic

5 Involvement of axillae/groins

e.g. hidradenitis suppurativa

4 Nail involvement



Psoriatic changes in nails and peri-ungual involvement

3 Involvement of hands, including nail folds and finger webs

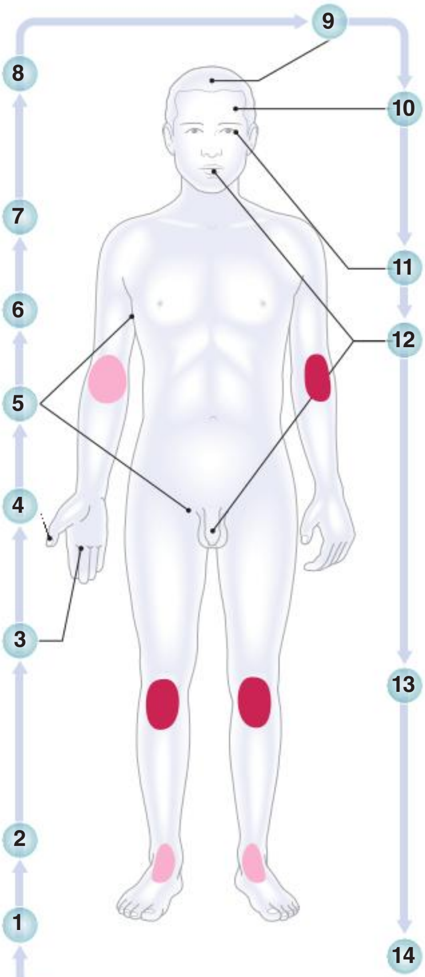
2 If symmetrical

🟥 Extensor, e.g. psoriasis

🟪 Flexor, e.g. eczema

1 Distribution of rash

Symmetrical vs asymmetrical
Proximal vs distal vs facial
Localised vs widespread



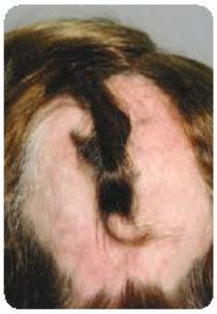
Observation

The patient must be undressed, with make-up and dressings removed, and examined in good lighting. Consider the following:

- Age
- General health
- Distress
- Scratching

9 Examination of scalp

Hair loss
Scalp changes



Alopecia areata

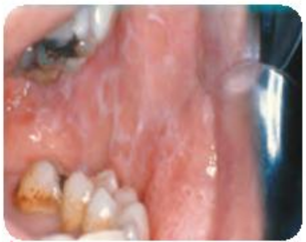
10 Involvement of face

Central
Hairline
Cheeks and nasal bridge: 'butterfly' distribution
Sparing of light-protected sites, e.g. behind ears, under chin

11 Eye involvement

e.g. Conjunctivitis/blepharitis in rosacea or eyelash loss in alopecia areata

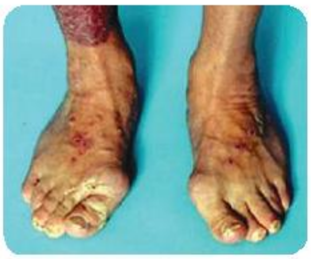
12 Oral and genital involvement



Reticulate (lacy) network on buccal mucosa in lichen planus. May also be genital involvement

13 Joint involvement

e.g. Psoriatic arthritis



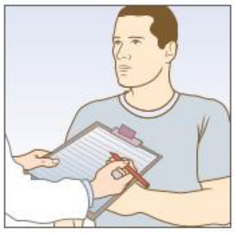
Arthritis, plaque psoriasis and psoriatic nail dystrophy

14 General medical examination

Including lymph nodes and other systems as indicated

It is tempting to examine the skin first. This is a mistake; take a history, then examine the skin and the rest of the patient.

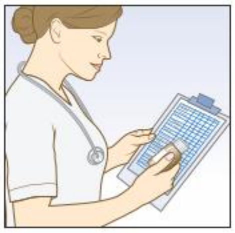
1. History-taking



Include:

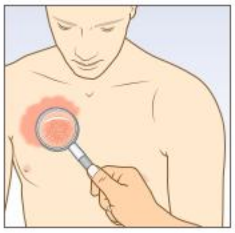
- Onset and course
- Exacerbating/relieving factors
- Past history of skin disease, atopy or autoimmune disease
- Social history, occupation, recreation
- Psychological impact, gauged by health-related quality-of-life indices

2. Drug/allergy history



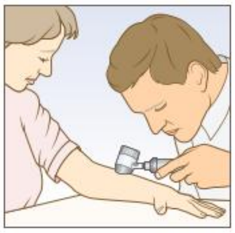
- Always take a detailed drug and allergy history
- Include all systemic and topical drugs, and over-the-counter preparations

3. Examination of skin



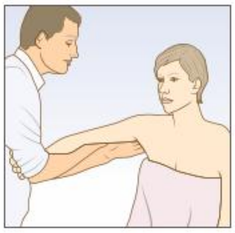
- Examine skin, hair, nails and mucous membranes
- Is it a rash or a lesion?
- Distribution and morphology important for rash

4. Closer inspection



- Use of a magnifying lens and/or dermatoscope may be invaluable
- Site, size and detailed morphology of a lesion are essential factors to elicit

5. General examination

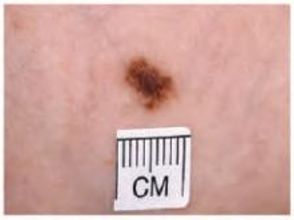


- General examination, incl. peripheral lymph nodes, may be indicated/important
- Skin diseases may have systemic features (e.g. cardiovascular disease in psoriasis); many systemic diseases have dermatological features (e.g. diabetes)

6. Define type of lesion using correct terminology

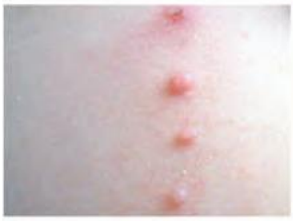
Helps in differential diagnosis and allows colleagues to visualise the process. Other definitions are provided in the chapter.

Macule/patch



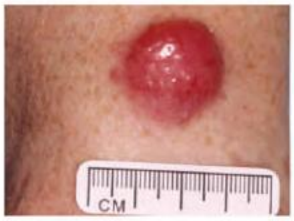
Macule: circumscribed flat area of colour change ≤ 1 cm diameter; patch: > 1 cm

Papule



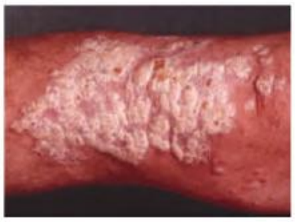
Discrete elevation ≤ 1 cm diameter

Nodule



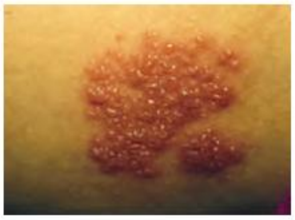
Like papule but deeper (into dermis or subcutaneous layer), > 1 cm diameter

Plaque



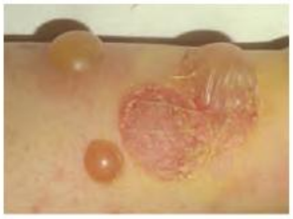
Raised area > 1 cm diameter with flat top

Vesicle



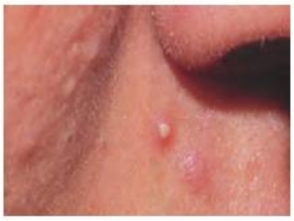
Small (≤ 1 cm diameter) fluid-filled blister

Blisters/bullae



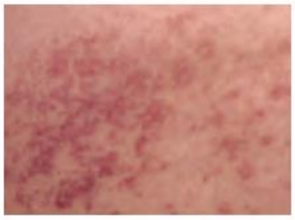
Large (> 1 cm diameter) fluid-filled blister

Pustule



Visible accumulation of pus in blister

Petechiae/purpura



Petechiae: tiny macules due to extravascular blood in dermis; purpura: larger, may be palpable

7. Score activity

Tools for objective assessment of disease severity, such as the Psoriasis Area and Severity Index (PASI), are important in assessing severity and treatment responses.

🟧 Four body parts are each scored individually

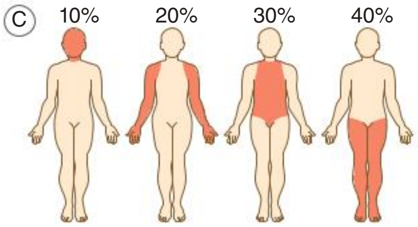
Ⓐ Each of the four body parts is scored:

Redness (erythema)	0–4
Thickness (induration)	0–4
Scaling (desquamation)	0–4

Ⓑ The area of each involved body part is scored:

0	0%
1	< 10%
2	10%–29%
3	30%–49%
4	50%–69%
5	70%–89%
6	90%–100%

Ⓒ



To find the PASI score, add together: (A) Sum for each part × (B) % of that part involved × (C) % weighting of that body part

Minimum = 0; maximum = 72

Diseases affecting the skin are common and important. The alteration or loss of normal skin function may not only severely impair quality of life but can sometimes be life-threatening. This may be exacerbated by the stigma associated with skin disease, often brought about by the ill-informed beliefs of others with respect to skin diseases, particularly with regards to visually disfiguring skin changes or the misguided thoughts that they are contagious. Skin diseases affect all ages and there are more than 2000 different types and presentations. Assessment of the skin is valuable in the management of anyone presenting with a medical problem and, conversely, assessment of other body systems is important when managing primary skin diseases. This chapter concentrates on common skin diseases and those that are important components of general medical conditions. Skin infections, including those related to the human immunodeficiency virus (HIV), tuberculosis, leprosy (Hansen disease) and syphilis, are also discussed in Chapters 14, 17, 14 and 15, respectively.

Functional anatomy and physiology

The skin covers just under 2 m^2 in the average adult. The outer layer is the epidermis, a stratified squamous epithelium consisting mainly of keratinocytes. The epidermis is attached to, but separated from, the underlying dermis by the basement membrane. The dermis is less cellular and supports blood vessels, nerves and epidermal-derived appendages (hair follicles and sweat glands). Below this is the subcutis, consisting of adipose tissue.

Epidermis

In most sites, the epidermis is only 0.1–0.2 mm thick, except on the palms or soles, where it can be several millimetres thick. Keratinocytes make up approximately 90% of epidermal cells (Fig. 26.1). The main proliferative compartment is the basal layer. Keratinocytes synthesise a range of structural proteins, such as keratins, loricrin and filaggrin (filament aggregating protein), which play key roles in maintaining the skin's barrier function. Keratinocytes are also responsible for synthesis of vitamin D on exposure to ultraviolet B (UVB) light. There are more than 50 types of keratins, and their expression varies by body site, site within the epidermis and disease state. Mutations of certain keratin genes can result in blistering disorders and ichthyosis (characterised by scale without major inflammation). As keratinocytes migrate from the basal layer, they differentiate, producing a variety of protein and lipid products. Keratinocytes undergo apoptosis in the granular layer, before losing their nuclei and becoming the flattened corneocytes of the stratum corneum (keratin layer). The epidermis is a site of lipid production, and the ability of the stratum corneum to act as a hydrophobic barrier is the result of its 'bricks and mortar' design; dead corneocytes with highly cross-linked protein membranes ('bricks') lie within a metabolically active lipid layer synthesised by keratinocytes ('mortar'). Terminal differentiation of keratinocytes relies on the keratin filaments being aggregated and this is, in part, mediated by filaggrin. Mutations of the filaggrin gene are found in ichthyosis vulgaris and in some patients with atopic eczema.

The skin is a barrier against physical stresses and infections. Cell-to-cell attachments must be able to transmit and dissipate stress, a function performed by desmosomes. Diseases that affect desmosomes, such as pemphigus, result in blistering due to keratinocyte separation.

The remaining 10% of epidermal cells are:

- *Langerhans cells*: these are dendritic, bone marrow–derived cells that circulate between the epidermis and local lymph nodes. Their prime function is antigen presentation to lymphocytes. Other dermal antigen-presenting dendritic cells are also present.
- *Melanocytes*: these occur predominantly in the basal layer and are of neural crest origin. They synthesise the pigment melanin from tyrosine, package it in melanosomes and transfer it to surrounding keratinocytes via their dendritic processes.
- *Merkel cells*: these occur in the basal layer and are thought to play a role in signal transduction of fine touch. Their embryological derivation is unclear.

Basement membrane

The basement membrane (see Fig. 26.1) is an anchor for the epidermis and allows movement of cells and nutrients between dermis and epidermis. The cell membrane of the epidermal basal cell is attached to the basement membrane via hemi-desmosomes. The lamina lucida lies immediately below the basal cell membrane and is composed predominantly of laminin. Anchoring filaments extend through the lamina lucida to attach to the lamina densa. This electron-dense layer consists mostly of type IV collagen; from it extend loops of type VII collagen, forming anchoring fibrils that fasten the basement membrane to the dermis.

Dermis

The dermis is vascular and supports the epidermis structurally and nutritionally. It varies in thickness from just over 1 mm on the inner forearm to 4 mm on the back. Fibroblasts are the predominant cells, but others include mast cells, mononuclear phagocytes, T lymphocytes, dendritic cells, neurons and endothelial cells. The acellular part of the dermis consists mainly of collagen I and III, elastin and reticulin, synthesised by fibroblasts. Support is provided by an amorphous ground substance (mostly glycosaminoglycans, hyaluronic acid and dermatan sulphate), whose production and catabolism are altered by hormonal changes and ultraviolet radiation (UVR). Based on the pattern of collagen fibrils, the superficial dermis is termed the 'papillary dermis', and the deeper, coarser part is the 'reticular dermis'.

Epidermal appendages

Hair follicles

There are 3–5 million hair follicles, epidermal invaginations that develop during the second trimester. They occur throughout the skin, except for palms, soles and parts of the genitalia (glabrous skin). The highest density of hair follicles is on the scalp (500–1000/cm^2). Newborns are covered with fine 'lanugo' hairs, which are usually non-pigmented and lack a central medulla; these are subsequently replaced by vellus hair, which is similar but more likely to be pigmented. By contrast, scalp hair becomes terminal hair, which is thicker with a central medulla, is usually pigmented and grows longer. At puberty, vellus hairs in hormonally sensitive regions, such as the axillary and genital areas, become terminal hairs.

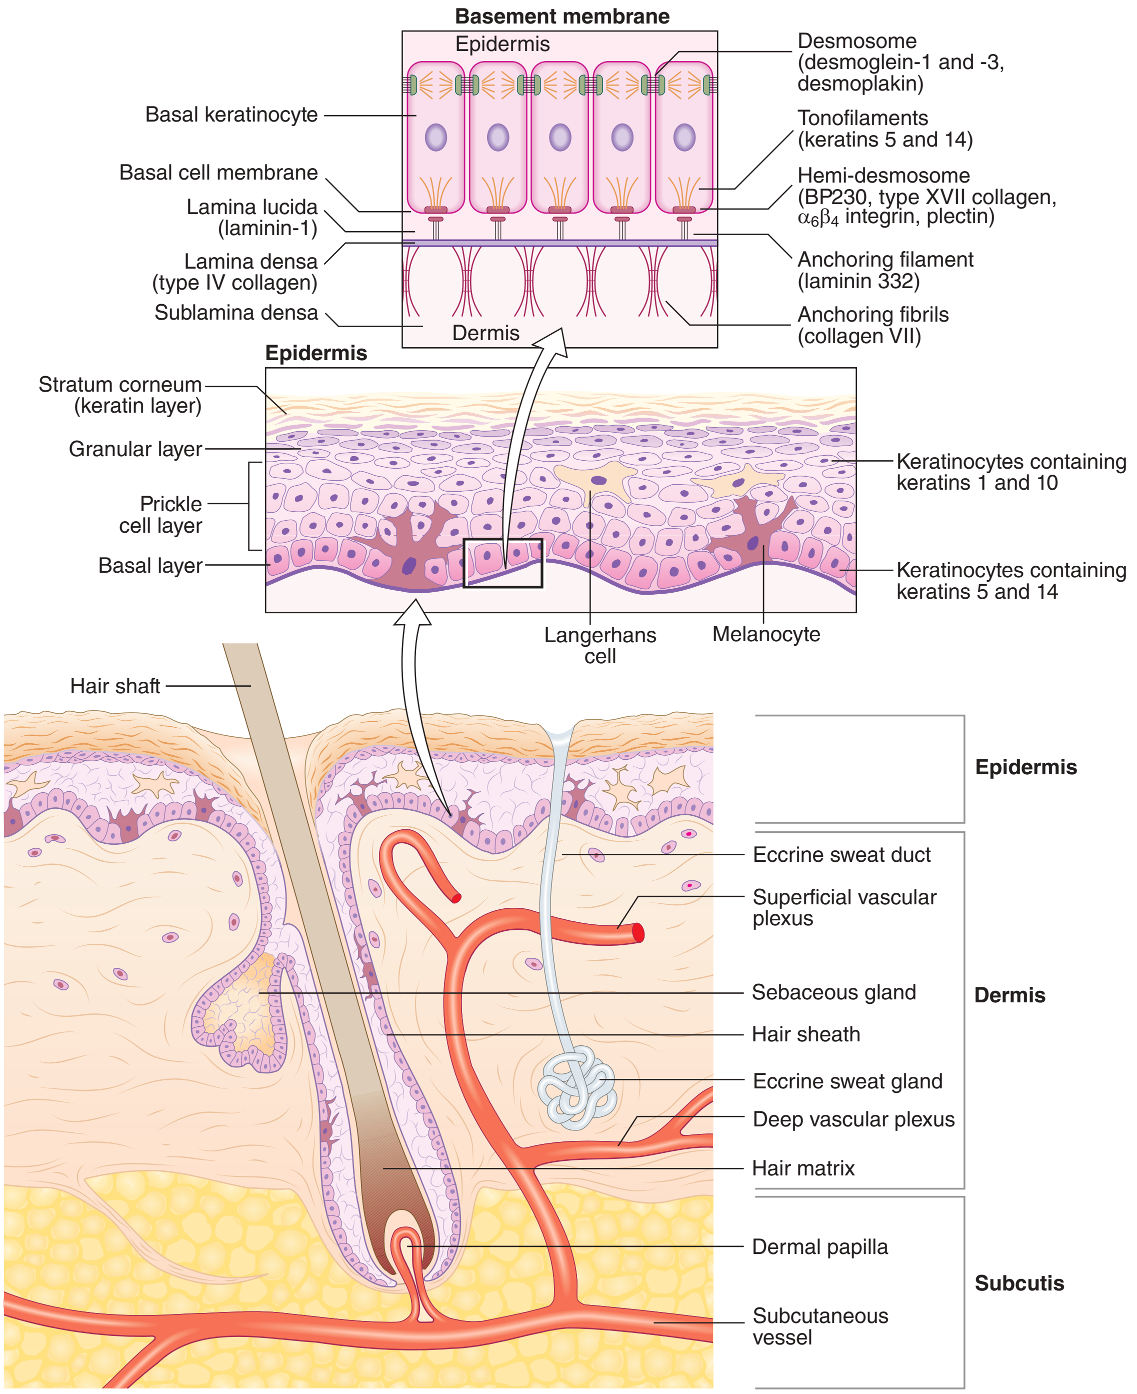
Human hairs grow in a cycle with three phases: anagen (active hair growth), catagen (transitional phase) and telogen (resting phase). The duration of each phase varies by site. On the scalp, anagen lasts several years, catagen a few days and telogen around three months. The length of hair at different sites reflects the differing lengths of anagen.

Sebaceous glands

Sebaceous glands are epidermal down-growths, usually associated with hair follicles and composed of modified keratinocytes. The cells of the sebaceous gland (sebocytes) produce a range of lipids, discharging the contents into the duct around the hair follicle. Sebum excretion is under hormonal control, with androgens increasing it (as do progesterones, to a lesser degree) and oestrogens reducing it. In animals, sebum is important for hair waterproofing but its role in humans is unclear.

Sweat glands

Eccrine sweat glands develop in the second trimester and are epidermal invaginations found all over the body. Their coiled ducts open directly on to the skin surface. They play a major role in thermoregulation and, unusually, are innervated by cholinergic fibres of the sympathetic nervous system. Eccrine glands of the palms and soles are innervated differently and are activated in the 'fight or flight' response. Apocrine sweat glands are restricted to the axillae and the mammary and genital areas, are connected to hair follicles and are not involved in thermoregulation.



Basement membrane
Epidermis
Desmosome (desmoglein-1 and -3, desmoplakin)
Basal keratinocyte
Tonofilaments (keratins 5 and 14)
Basal cell membrane
Hemi-desmosome (BP230, type XVII collagen, $\alpha_6\beta_4$ integrin, plectin)
Lamina lucida (laminin-1)
Lamina densa (type IV collagen)
Anchoring filament (laminin 332)
Sublamina densa
Dermis
Anchoring fibrils (collagen VII)
Epidermis
Stratum corneum (keratin layer)
Granular layer
Keratinocytes containing keratins 1 and 10
Prickle cell layer
Basal layer
Keratinocytes containing keratins 5 and 14
Langerhans cell
Melanocyte
Hair shaft
Epidermis
Eccrine sweat duct
Superficial vascular plexus
Sebaceous gland
Dermis
Hair sheath
Eccrine sweat gland
Deep vascular plexus
Hair matrix
Dermal papilla
Subcutis
Subcutaneous vessel

Fig. 26.1 Structure of normal skin.

Nails

Fingernail growth commences at approximately eight weeks of gestation and is complete by 32 weeks. Toenails develop slightly later. The anatomy of the nail apparatus is described later in the chapter.

Blood vessels and nerves

Human skin has a plentiful blood supply, arranged in superficial and deep plexuses consisting of arterioles, arterial and venous capillaries, and venules. The upper plexus in the papillary dermis communicates with the lower plexus at the junction between the dermis and the subcutis. Capillary loops arise from terminal arterioles in the horizontal papillary plexus. Blood vessels are supplied by sympathetic and parasympathetic nerves, with the relative contributions of the pathways differing by site. Sympathetic signals are important in mediating autonomic-induced vasoconstriction. The blood supply of skin is far greater than that required for normal skin physiology and reflects the importance of the skin in thermoregulation.

Functions of the skin

The skin has many functions, all of which can be affected by disease (Box 26.1). Skin changes associated with ageing are shown in Box 26.2.

Investigation of skin disease

Magnifying glass

A hand-held or freestanding magnifying lens used under good lighting conditions (ideally daylight) is valuable for examination of the skin.

Wood's light

Wood's light is a long-wavelength UVA/short-wavelength visible (violet) light source that can be used in various ways. In hypopigmentation, such as in vitiligo, it can help in appreciating the extent of disease. In pigmented conditions, such as melasma, it can determine whether pigmentation is mainly epidermal (sharp cut-off under Wood's lamp) or mixed epidermal and dermal (ill-defined cut-off). Wood's lamp can also be used to help with the diagnosis of some fungal infections because of their characteristic fluorescence.

Dermatoscopy and diascopy

Dermatoscopy (also known as dermoscopy and epiluminescence microscopy) is widely performed with hand-held dermatoscopes. What makes dermatoscopy unique is the fact that it allows visualisation through contact of a glass plate on the instrument with a liquid film applied to the skin, or through special optics to allow non-contact dermatoscopy, enabling deeper structures to be seen without interference from reflection and refraction of light in the epidermis.

Diascopy is simply pressing on the lesion with a glass slide. This provides some of the effect of dermatoscopy but is mainly used to remove blood from vascular lesions to make the appearance of the lesion clearer. Granulomatous skin diseases may have a characteristic appearance under diascopy, such as in lupus vulgaris (cutaneous tuberculosis), in which 'apple jelly nodules' are typically seen on diascopy.

Skin biopsy

Skin biopsy is a pivotal investigation in dermatology and can be used in a range of dermatological presentations. In the most common scenario, a skin biopsy is undertaken to obtain tissue on which to perform standard histopathology. However, tissue may also be subjected to a variety of staining and culture techniques, including immunostaining. Histopathological examination of skin biopsies is especially useful for tumour diagnosis. When a dermatologist or pathologist with dermatopathology expertise is involved, it can also assist in the diagnosis of inflammatory skin diseases. It is rare for histopathology of a previously undiagnosed inflammatory skin disease to provide a diagnosis on its own; clinico-pathological correlation is critical. Most biopsies are stained with haematoxylin and eosin, but other stains may be useful in special situations, such as for fungal hyphae, iron or mucin. Direct immunofluorescence can also be undertaken on a fresh skin biopsy, allowing antigen visualisation using fluorescein-labelled antibodies, which is especially important in the diagnosis of autoimmune bullous disorders or connective tissue disease, such as cutaneous lupus.

Microbiology

Bacteriology

Bacterial swabs may identify a causative infective agent. However, organisms identified from the skin surface may not be the cause of the skin disease, but instead may simply reflect colonisation of skin that has already been damaged by a primary skin disease.

Virology

Several techniques, including immunofluorescence and polymerase chain reaction (PCR), are available to diagnose viral infections from vesicle fluid, such as with herpes simplex or herpes zoster virus.

Mycology

Scale, nail clippings (or scrapings of crumbly subungual hyperkeratosis) and plucked hairs can be examined by light microscopy. If potassium hydroxide and a simple light microscope are available, this can be performed in any outpatient clinic. Microbiology laboratories will also routinely undertake microscopy and culture for fungi and yeasts.

26.1 Functions of the skin

Function	Structure/cell involved
Protection against	
Chemicals, particles, desiccation	Stratum corneum
Ultraviolet radiation	Melanin produced by melanocytes and transferred to keratinocytes Stratum corneum hyperproliferation
Antigens, haptens	Langerhans cells, lymphocytes, mononuclear phagocytes, mast cells, dermal dendritic cells
Microorganisms	Stratum corneum, Langerhans cells, mononuclear phagocytes, mast cells, dermal dendritic cells
Maintenance of fluid balance	
Prevents loss of water, electrolytes and macromolecules	Stratum corneum
Shock absorber	
Strong, elastic and compliant covering	Dermis and subcutaneous fat
Sensation	Specialised nerve endings mediating pain and withdrawal Itch leading to scratch and removal of a parasite
Metabolism Detoxification of xenobiotics, retinoid metabolism, isomerisation of urocanic acid	Predominantly keratinocytes
Temperature regulation	Eccrine sweat glands and blood vessels
Protection, and fine manipulation of small objects	Nails
Hormonal	
Steroidogenesis, testosterone synthesis and conversion to other androgenic steroids	Hair follicles, sebaceous glands
Conversion of thyroxine (T4) to triiodothyronine (T3)	Keratinocytes
Conversion of 7-dehydrocholesterol to vitamin D	Keratinocytes
Pheromonal	
Importance unknown in humans	Apocrine sweat glands, possibly sebaceous glands
Psychosocial, grooming and sexual behaviour	Appearance, tactile quality of skin, hair, nails

26.2 Skin changes in old age

- **Chronological ageing**: due to the intrinsic ageing process.
- **Photo-ageing**: due to cumulative ultraviolet radiation (UVR) exposure and superimposed on intrinsic ageing.
- **Typical changes**: include atrophy, laxity, yellow discoloration, wrinkling, dryness, irregular pigmentation, and thinning and greying of hair.
- **Causes**: age-related alterations in structure and function of the skin, cumulative effects of environmental insults, especially UVR and smoking, cutaneous consequences of disease in other organ systems.
- **Consequences**: reduction in immune and inflammatory responses, reduction in absorption and clearance of topical medications, reduced healing, increased susceptibility to irritants, dermatitis, adverse drug effects (including topical glucocorticoid-induced atrophy and purpura) and diseases such as skin cancer.

Patch testing

Patch testing is the investigation of choice for delayed, cell-mediated, type IV hypersensitivity reactions to topical agents, which clinically manifest as dermatitis. Potential allergens (see Box 26.22) are applied as patches to the back under occlusion for 48 hours, in vehicles and at concentrations that minimise false-positive and false-negative reactions. After 48 hours the patches are removed and patch-test readings are undertaken at time points of up to 7 days after patch-test application, with the most typical time point being at 96 hours. When interpreting patch test readings, it is important to determine the clinical relevance of any allergic reactions before giving avoidance advice.

Photopatch testing is like patch testing but investigates delayed hypersensitivity reactions to a topically applied agent (usually a sunscreen or topical non-steroidal anti-inflammatory drug (NSAID)) after the absorption of UVR. It involves applying substances in duplicate and irradiating one set with UVR (typically UVA, 5 J/cm^2), readings then being conducted in a similar manner to patch testing.

Specific immunoglobulin E testing and prick tests

Specific immunoglobulin E (IgE) levels to antigens can be measured in serum as part of the investigation of potential cutaneous type I (immediate) hypersensitivity reactions to various antigens such as inhaled allergens, e.g. pollen or house dust mite, or foodstuffs. Alternatively, prick tests may be considered, where skin is pricked with commercially available stylets through a dilution of the appropriate antigen solution. However, if challenge tests are undertaken for patients with suspected allergy, these must be performed under controlled conditions with appropriate support in place, due to the potential risk of triggering a severe reaction. More details of IgE testing are provided in Chapter 4.

Phototesting

Phototesting is important in the assessment of suspected photosensitivity. The mainstay investigation is monochromator phototesting, which involves exposing the patient's back to increasing doses of irradiation using narrow wavebands across the solar spectrum and then assessing responses at each waveband, using the minimal erythema dose (MED) as the endpoint. This is the dose required to cause just perceptible skin reddening (erythema) and is compared with values for the normal population. If a patient has reduced MEDs (develops erythema at lower doses than healthy subjects), this indicates abnormal photosensitivity. Thus, monochromator phototesting can be used to determine whether a patient is abnormally photosensitive, which wavebands are involved and how sensitive the patient is. Provocation testing can be performed with a broadband (usually UVA) source to induce rash at a test site (most useful for polymorphic light eruption) and is a helpful diagnostic test. Provocation testing to a variety of light sources, including artificial compact fluorescent lamps, may also be indicated, the latter being most relevant in patients with severe photosensitivity.

Patients who are referred for phototherapy will also commonly undergo a MED test, in which they are exposed to a series of test doses of the light source that will be used therapeutically (often narrowband UVB); the MED is determined 24 hours later (or 72–96 hours for the psoralen–ultraviolet A (PUVA) minimal phototoxic dose). This allows treatment regimens to be individualised, based on a patient's erythemal responses. The MED can also detect abnormal photosensitivity and represents a safety measure prior to starting a course of phototherapy.

Blood tests

Although most patients presenting with a skin problem do not need blood tests as part of their investigations, there are many systemic diseases that can present with skin features and, indeed, blood tests may also be indicated in the investigation of primary skin disease. A wide range of possible investigations may be required, some examples include haemoglobin, iron studies and thyroid function tests in pruritus or hair loss; autoantibody screening if lupus is suspected; measurement of porphyrins for skin fragility and hypertrichosis; and hepatitis screening in lichen planus. These diverse examples emphasise the importance of considering an underlying systemic disease when assessing a patient with a dermatological presentation.

Imaging

Imaging techniques are not typically required but X-rays, ultrasound, magnetic resonance imaging (MRI) or computed tomography (CT) may occasionally be indicated in specific situations, such as in metastatic melanoma or in a patient presenting with a diagnosis of cutaneous sarcoid.

Presenting problems in skin disease

The major presentations in dermatology are outlined below. Detail of the underlying disorders is mostly provided in the disease-specific sections further on in the chapter.

Lumps and lesions

The term lump or lesion is typically used to describe a papule or nodule, although sometimes it may refer to a macule or plaque. A new or changing lump is one of the key dermatology presentations.

Clinical assessment

Detailed history-taking and examination are essential:

- *Change*: Is the lump new or has there been a change in a pre-existing lesion? What is the nature of the change – size, colour, shape or surface change? Has change been rapid or slow? Are there other features – pain, itch, inflammation, bleeding or ulceration (definition of 'ulcer': an area from which the epidermis and at least the upper part of the dermis have been lost – see Fig. 26.9)?
- *Patient*: What is the patient's age? Are they fair-skinned and freckled? Have they got multiple naevi? Has there been much sun exposure? Have they used sunbeds or lived and worked in sunny climates? Have they used photoprotection? Have they had skin cancer before or is there a family history of skin cancer? What medications are they taking? Are they immunosuppressed?
- *Site*: Is it on a sun-exposed or covered site? The scalp, face, upper limbs and back in men, and face, hands and lower legs in women, are the most chronically sun-exposed sites.
- *Are there other similar lesions?* These might include actinic keratoses (see Fig. 26.14) or basal cell papillomas (see Fig. 26.18).
- *Morphology*: Tenderness, size, symmetry, regularity of border, colour, surface characteristics and the presence of features such as crust (definition: dried exudate of blood or serous fluid – see Fig. 26.20), scale (definition: a flake arising from the stratum corneum; any condition with a thickened stratum corneum can cause scaling – see Fig. 26.14) and ulceration must be assessed. Stretching the skin and using a magnifying lens can be helpful, such as for detecting the raised, pearled edge of a basal cell carcinoma (see Fig. 26.12).
- *Dermatoscopy*: This can be used to detect the presence of abnormal vessels, such as in basal cell carcinoma, or the characteristic keratin cysts in basal cell papillomas (seborrhoeic keratoses). It is invaluable for assessing pigmented and vascular lesions (Fig. 26.2).

Is it a melanocytic naevus or a malignant melanoma?

This is a common clinical scenario and one that it is critical to resolve correctly.

- The precise nature of the change should be determined (as above). Listen to the patient and pay attention to subtle changes, as people know their skin well.

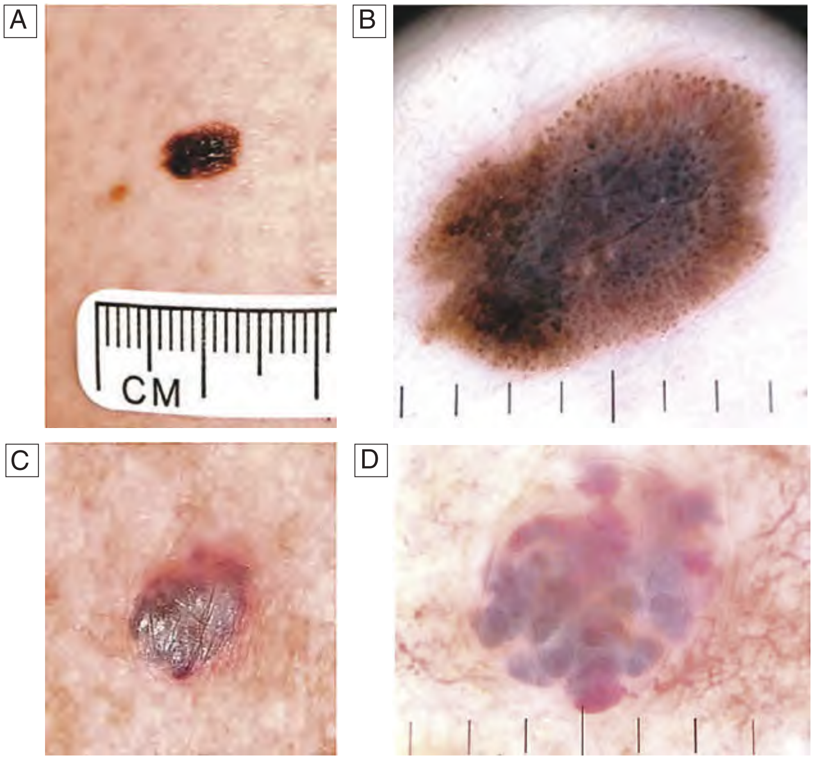


Fig. 26.2 **Dermatoscopy.** **A** A changing lesion. **B** Dermatoscopy highlights the abnormal pigment network and other features suggestive of melanoma. Excision biopsy confirmed the diagnosis of superficial spreading malignant melanoma (Breslow thickness 0.8 mm). **C** Another changing lesion. **D** Dermatoscopy highlights the vascular lacunae of this benign angioma, and the patient was reassured.

- If the patient has other pigmented lesions, then these should be examined too, as they may be informative. For example, if the presenting lesion looks different from the others, then suspicion of melanoma is increased; conversely, if the patient has multiple basal cell papillomas (seborrhoeic keratoses), this may be reassuring – although do not be falsely reassured.
- Is there a positive family history of melanoma? A suspicious naevus in a patient with a first-degree relative with melanoma probably warrants excision.

The 'ABCDE rule' is a guide to the characteristic features of melanoma (Box 26.3 and see Figs. 26.2 and 26.16), although melanomas should ideally be diagnosed before the diameter is greater than 0.5 cm. Loss of normal skin markings in a pigmented lesion may be suggestive of melanoma. Conversely, normal skin markings and fine hairs dispersed evenly over a lesion are reassuring but do not exclude melanoma. The Glasgow seven-point checklist is another useful guide:

- *major features*: change in size, shape and colour
- *minor features*: diameter > 0.5 cm, inflammation, oozing, bleeding, itch or altered sensation.

Patients with one major or one minor feature should be referred for further evaluation.

Investigations and management

If a benign diagnosis, such as basal cell papilloma (seborrhoeic keratosis), is made on clinical grounds, then the patient can be reassured and the lesion either left or treated, for example, with cryotherapy. If there are concerns about the diagnosis or malignancy is suspected, then skin biopsy to obtain a tissue diagnosis is the usual approach. An incisional biopsy may be indicated, although if the lesion is small, excision may be most appropriate. If concern exists about the possibility of malignant melanoma, initial excision with a 2–5 mm margin would usually be undertaken prior to more definitive management once histology was confirmed. Further management of a changed lesion would, of course, depend on histological analysis of the diagnostic biopsy.

i 26.3 ABCDE features of malignant melanoma

- **A**symmetry
- **B**order irregular
- **C**olour irregular
- **D**iameter >0.5 cm
- **E**levation irregular

(+ Loss of skin markings)

Rash

A rash is the other common presentation in dermatology. The main categories of scaly rashes are listed in Box 26.4. The most common type of rash presentation is maculopapular. Diagnosis can often be made on clinical grounds, although a diagnostic biopsy may be required.

Clinical assessment

Important aspects of the history include:

- *Age at onset and duration of rash*. Atopic eczema often starts in early childhood and psoriasis between 15 and 40 years, and both may be chronic. Infective or drug-induced rashes are more likely to be of short duration and the latter to occur in relation to drug ingestion. Duration of individual lesions is also important, as in urticaria,

26.4 Causes and clinical features of common scaly rashes

Diagnosis	Distribution	Morphology	Associated signs
Atopic eczema (p. 1127)	Face and flexures	Poorly defined erythema, scaling Vesicles Lichenification if chronic	Shiny nails Infra-orbital crease 'Dirty neck' (grey–brown discoloration)
Psoriasis (p. 1129)	Extensor surfaces Lower back	Well-defined Erythematous plaques Silvery scale	Nail pitting, onycholysis Scalp involvement Axillae and genital areas often affected Joint involvement Köbner phenomenon (p. 1133)
Pityriasis rosea (p. 1132)	'Fir tree' pattern on trunk	Well-defined Small, erythematous plaques Collarette of scale	Herald patch
Drug eruption (p. 1132)	Widespread	Macules and papules Erythema and scale Exfoliation	Possible mucosal involvement or erythroderma
Pityriasis versicolor (p. 1122)	Upper trunk and shoulders	Hypo- and hyper-pigmented scaly patches	
Lichen planus (p. 1132)	Distal limbs Flexural aspect of wrists Lower back	Shiny, flat-topped, violaceous papules Wickham striae	White, lacy network on buccal mucosa Nail changes Scarring alopecia Köbner phenomenon
Tinea corporis (p. 1122)	Asymmetrical Often isolated lesions	Erythematous, often annular plaques Peripheral scale (sometimes pustules) Expansion with central clearing	Possible nail, scalp, groin involvement
Secondary syphilis (p. 413)	Trunk and proximal limbs Palms and soles	Red macules and papules, which become 'gun-metal' grey	History of chancre Systemic symptoms, e.g. malaise and fever

for example, where lesions will come and go over short periods of time and do not persist beyond 24 hours.

- *Body site at onset and distribution*. Flexural sites are more typically involved in atopic eczema, and extensor surfaces and scalp in psoriasis. Symmetry is often indicative of an endogenous disease, such as psoriasis, whereas asymmetry is more common with exogenous causes, such as contact dermatitis or infections like herpes zoster.
- *Itch*. Eczema is usually extremely itchy, and psoriasis may be less so.
- *Preceding illness and systemic symptoms*. Guttate psoriasis may be precipitated by a β-haemolytic streptococcal throat infection; almost all patients with infectious mononucleosis treated with amoxicillin will develop an erythematous maculopapular eruption; a history of chancre at the site of inoculation may be elicited in a presentation of secondary syphilis; malaise and arthralgia are common in drug eruptions and vasculitis.

The morphology of the rash and the characteristics of individual lesions are important (see Box 26.4).

Investigations and management

It is important to have a short differential diagnosis based on clinical assessment to guide investigations. For example, in psoriasis, no investigations may be needed and initial management with patient counselling and topical therapies may suffice. If the diagnosis is unclear, then a diagnostic skin biopsy and other targeted investigations based on the clinical picture may be required. An initial management plan should also be implemented. For example, in a child presenting with a rash that has features suggestive of impetigo, skin and nasal swabs should be performed and, once these have been taken, topical or systemic antibiotics should be introduced, depending on clinical extent of disease, and management should be adjusted accordingly, dependent on investigation findings and clinical course. In contrast, if a patient presents with a maculopapular rash shortly after introduction of a new drug, then drug withdrawal, diagnostic biopsy, full blood count, including eosinophil count, and liver and renal function tests, in parallel with topical emollients and glucocorticoids, may be indicated.

26.5 Causes of acquired blisters

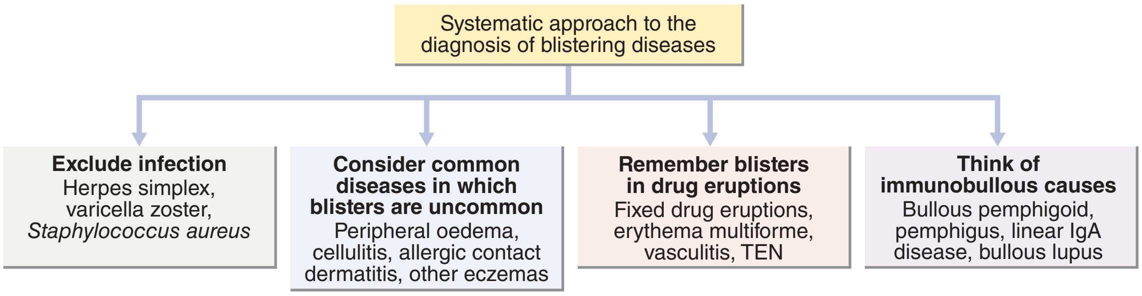
	Localised	Generalised
Vesicular	Herpes simplex Herpes zoster Impetigo Pompholyx	Eczema herpeticum* Dermatitis herpetiformis Acute eczema
Bullous	Impetigo Cellulitis Stasis oedema Acute eczema Insect bites Fixed drug eruption	Toxic epidermal necrolysis* Erythema multiforme Stevens–Johnson syndrome* Bullous pemphigoid Pemphigus* Epidermolysis bullosa acquisita Lupus erythematosus Porphyria cutanea tarda Pseudoporphyria Drug eruptions

*Usually with mucosal involvement too.

Blisters

A blister is a fluid-filled collection in the skin. The term vesicle is used for small lesions and bulla for larger lesions. Blistering occurs due to loss of cell adhesion within the epidermis or subepidermal region (see Fig. 26.1). The clinical presentation depends on the site or level of blistering within the skin, which in turn reflects the underlying cause. There are a limited number of conditions that present with blisters (Box 26.5):

- Intact blisters are not often seen if the split is high in the epidermis (below the stratum corneum), as the blister roof is so fragile that it



Systematic approach to the diagnosis of blistering diseases
Exclude infection
Herpes simplex, varicella zoster, *Staphylococcus aureus*
Consider common diseases in which blisters are uncommon
Peripheral oedema, cellulitis, allergic contact dermatitis, other eczemas
Remember blisters in drug eruptions
Fixed drug eruptions, erythema multiforme, vasculitis, TEN
Think of immunobullous causes
Bullous pemphigoid, pemphigus, linear IgA disease, bullous lupus

Fig. 26.3 **A systematic approach to the diagnosis of blistering diseases.** (TEN = toxic epidermal necrolysis)

ruptures easily, leaving erosions (definition: an area of skin denuded by complete or partial loss of the epidermis). This occurs in pemphigus foliaceus, staphylococcal scalded skin syndrome (see Fig. 26.21) and bullous impetigo.

- If the split is lower in the epidermis, then intact flaccid blisters and erosions may be seen, as occurs in pemphigus vulgaris and toxic epidermal necrolysis (see Fig. 26.41).
- If the split is subepidermal, then tense-roofed blisters are seen. This occurs in bullous pemphigoid (see Fig. 26.42), epidermolysis bullosa acquisita and porphyria cutanea tarda (see Fig. 26.53).
- If there are foci of separation at different levels of the epidermis, such as may occur in eczema, then multilocular bullae made up of coalescing vesicles can occur.

Clinical assessment

Detailed history-taking and examination are critical. A history of onset, progression, mucosal involvement, drugs and systemic symptoms should be sought. Clinical assessment of the distribution, extent and morphology of the rash should be made. The Nikolsky sign is useful: sliding lateral pressure from a finger on normal-looking epidermis can dislodge and detach the epidermis in conditions with intra-epidermal defects, such as pemphigus and toxic epidermal necrolysis. A systematic approach to diagnosis is required (Fig. 26.3).

Investigations and management

Investigations and initial management will be guided by the clinical presentation and differential diagnosis and are described in more detail under the specific diseases. For example, an initial approach may include an incisional diagnostic skin biopsy for histology and direct immunofluorescence, indirect immunofluorescence and other targeted blood tests or skin swabs. Management should be based on the likely diagnosis and begin in parallel with investigations, until the diagnosis is confirmed.

Itch (pruritus)

Itch describes the unpleasant sensation that leads to scratching or rubbing. The terms ‘itch’ and ‘pruritus’ are synonymous; however, ‘pruritus’ is often used when itch is generalised. Itch can arise from primary cutaneous disease or be secondary to systemic disease, which may cause itch by central or peripheral mechanisms. Even when the mechanism is peripheral, there are not always signs of primary skin disease.

The nerve endings that signal itch are in the epidermis or near the dermo-epidermal junction. The underlying mechanisms of itch are not fully understood. Transmission is by unmyelinated slow-conducting C fibres through the spinothalamic tract to the thalamus and then the cortex. Aδ fibres also seem to be involved in transmitting signals to the spinal cord, and the heat-sensitive transient receptor potential (TRP) channels 1–4 are important. There is an inhibitory relationship between pain and itch. Scratching may relieve the symptom of itch after the sensation has ceased and this is either by stimulation of ascending sensory pathways that inhibit itch-transmitting neurons at the spinal cord (Wall’s ‘gate’ mechanism), or by direct damage to cutaneous sensory nerves.

26.6 Primary skin diseases causing pruritus

Generalised pruritus

- Scabies
- Eczemas
- Pre-bullous pemphigoid
- Urticarias
- Xeroderma of old age
- Psoriasis

Localised pruritus

- Eczemas
- Lichen planus
- Dermatitis herpetiformis
- Pediculosis
- Tinea infections

The mechanisms of itch in most systemic diseases remain unclear. The itch of kidney disease, for example, may be mediated by circulating endogenous opioids. The clinical observation that peritoneal dialysis helps reduce itch more frequently than haemodialysis is consistent with this, with smaller molecules generally being dialysed more readily if the peritoneal membrane is used rather than a haemodialysis membrane.

Clinical assessment

It is important to determine whether skin changes are primary (a process in the skin causing itch) or secondary (skin changes caused by rubbing and scratching because of itch). This requires a thorough history and examination, sometimes with investigations, to exclude systemic disease. Many common primary skin disorders are associated with itch (Box 26.6). If itch is not connected with primary skin disease, other causes should be considered (Box 26.7). These include liver diseases (mainly cholestatic diseases, such as primary biliary cholangitis), malignancies (generalised itch may be the presenting feature of lymphoma), haematological conditions (generalised itch in chronic iron deficiency or water contact–provoked (aquagenic) intense itch in polycythaemia), endocrine diseases (including hypo- and hyperthyroidism), chronic kidney disease (in which severity of itch is not always clearly associated with plasma creatinine concentration) and psychogenic causes (such as in ‘delusions of infestation’). Itch is common in pregnancy and may be due to one of the pregnancy-specific dermatoses. Making a correct diagnosis is particularly important in pregnancy, as some disorders can be associated with increased fetal risk (Box 26.8).

Investigations and management

Investigations should be directed towards finding an underlying cause and there will be a different approach for itch with rash, as opposed to itch with no signs of primary skin disease (Fig. 26.4). If there are no signs of primary skin disease, investigations should be undertaken to exclude systemic disease or iatrogenic causes. Psychogenic itch should be considered only if organic disease has been ruled out. There are no consistently effective therapies to suppress itch, and so establishing the underlying cause is critical. If a clear-cut diagnosis cannot be made, non-specific approaches can be used for symptom relief. These include sedation, often with H_1-receptor antihistamines, along

26.7 Secondary causes of pruritus

Medical condition	Cause of pruritus	Treatment*
Liver disease	Central opioid effect Elevation in bile salts may contribute	Naltrexone Colestyramine Rifampicin Sedative antihistamines UVB
Renal failure	Unknown; uraemia contributes	UVB Oral activated charcoal
Haematological disease		
Anaemia	Iron deficiency	Iron replacement
Polycythaemia rubra vera	Unknown (often aquagenic pruritus)	
Lymphoma Leukaemia Myeloma	Unknown	
Endocrine disease		
Diabetes mellitus	Infections such as candidiasis and tinea	Treatment of infection
Thyrotoxicosis	Unknown	
Hypothyroidism	Unknown	
Carcinoid syndrome	5-HT-mediated	
HIV infection	Infection, infestation Eosinophilic folliculitis Seborrhoeic dermatitis Unknown	Treatment of infection Local corticosteroids, UVB Anti-pityrosporal treatment UVB
Malignancy	Unknown	
Psychogenic	Unknown	Psychotherapy, anxiolytics, antidepressants

*In addition to specific treatment of the primary condition and symptomatic treatments, such as emollients. (5-HT = 5-hydroxytryptamine, serotonin; HIV = human immunodeficiency virus; UVB = ultraviolet B)

26.8 Causes of pruritus in pregnancy

Diagnosis	Pregnancy, gestation and features	Treatment
Polymorphic eruption of pregnancy (pruritic urticarial papules and plaques, PUPP)	Typically, first pregnancy and uncommonly recurs during third trimester and after delivery Polymorphic urticated papules and plaques, start in striae	Chlorphenamine, emollients Topical glucocorticoids
Acute cholestasis of pregnancy	Third trimester and commonly recurs in subsequent pregnancies Abnormal liver function tests Increased fetal and maternal risk	Emollients Chlorphenamine Colestyramine UVB Early delivery
Pemphigoid gestationis	Any stage, often second trimester and commonly recurs in subsequent pregnancies Urticated erythema, blistering initially periumbilical Characteristic histology and immunofluorescence	Topical or oral glucocorticoids
Prurigo gestationis	Second trimester Excoriated papules	Emollients Topical glucocorticoids Chlorphenamine UVB
Pruritic folliculitis	Third trimester Sterile pustules on trunk	Topical glucocorticoids UVB

(UVB = ultraviolet B)

with emollients and counterirritants (such as topical menthol-containing preparations). UVB phototherapy is useful for generalised itch due to a variety of causes, but the only randomised controlled study of efficacy is in chronic kidney disease. Other treatments include low-dose tricyclic antidepressants (probably through similar mechanisms to those involved when these drugs are used for chronic pain) and opiate antagonists. If a psychogenic itch is considered likely, antidepressants and/or cognitive behavioural therapy may be effective. Itch of any cause can be severe and its potentially major adverse effects on quality of life are not always fully appreciated. Assessments of impact on quality of life, such as Dermatology Life Quality Index (DLQI) scores, are essential.

Photosensitivity

Cutaneous photosensitivity is an abnormal response of the skin to ultraviolet (UV) or visible radiation. Sun is the natural source of UV radiation (UVR), but patients may also be exposed to artificial UVR sources through sunbeds and/or phototherapy. Chronic UVR exposure increases skin cancer risk and photo-ageing. Acute exposure can induce erythema (redness) as a normal response (Fig. 26.5). However, abnormal photosensitivity occurs when a patient reacts to lower doses than would normally cause a response, either with a heightened erythemal reaction or the development of a rash. Photo-aggravated skin diseases are exacerbated by sunlight but not caused by it. The main photosensitive and photo-aggravated diseases are listed in Box 26.9.

Sunlight consists mainly of visible light, and the UVR component is divided into three wavebands (Fig. 26.6), according to the Commission Internationale de l'Eclairage (CIE):

- *UVC* (200–280 nm), which is absorbed by ozone and does not reach the Earth's surface.
- *UVB* (280–315 nm), which constitutes less than 10% of UVR exposure but is around 1000-fold more potent than UVA and so accounts for the erythemal 'sunburning' effects of sunlight.
- *UVA* (315–400 nm), which is the most abundant UVR component reaching the Earth's surface.

The arbitrary division between UVB and UVA regions is more often considered by photobiologists to be at 320 nm, and the UVA region can be further subdivided into UVA2 (320–340 nm) and UVA1 (340–400 nm), with the latter being used therapeutically for skin conditions, such as morphoea (scleroderma) and eczema.

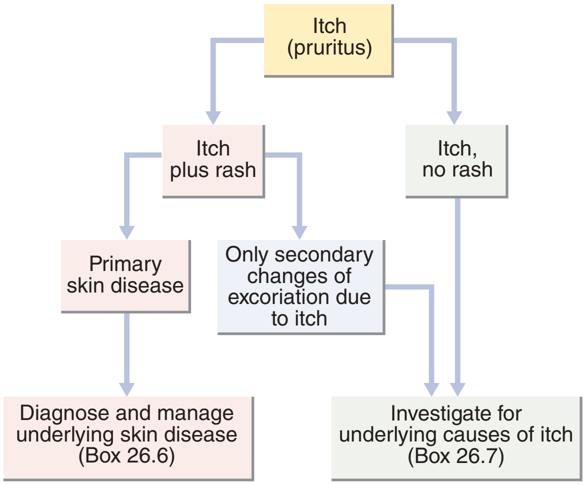


Fig. 26.4 **An overall approach to the investigation and management of itch (pruritus).**

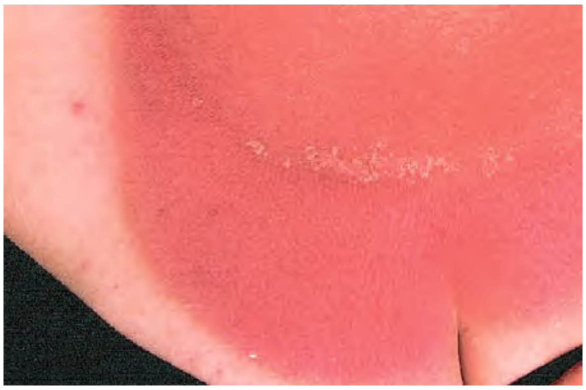

Fig. 26.5 **Sunburn.** Acute exposure to ultraviolet radiation results in an erythemal response that peaks 12–24 hours later. Sensitivity depends on the individual's constitutive skin phototype.

26.9 The photosensitivity and photo-aggravated diseases

Cause	Condition	Clinical features
Immunological (previously known as idiopathic)	Polymorphic light eruption (PLE)	Seasonal, itchy, papulovesicular rash on photo-exposed sites; face and back of hands often spared. Often hours of UVR exposure needed to provoke; lasts a few days; affects about 20% in Northern Europe, more common in young women
	Chronic actinic dermatitis (CAD)	Chronic dermatitis on sun-exposed sites. Most common in older adult males. Predominantly UVB, but also often UVA and visible light photosensitivity. Most also have contact allergies
	Solar urticaria	Immediate-onset urticaria on photo-exposed sites. Usually UVA and visible light photosensitivity. Can occur at any age
	Actinic prurigo	Uncommon, presents in childhood. Often familial, with strong HLA association. Some similarities to PLE, although scarring occurs
	Hydroa vacciniforme	Rare childhood photodermatosis. Varioliform scarring
Drugs (variety of mechanisms)	Phototoxicity	Usually UVA (and visible light) photosensitivity Most common. Exaggerated sunburn and exfoliation. Many drugs such as thiazides, tetracyclines, fluoroquinolones, quinine, NSAIDs
	Pseudoporphyria	NSAIDs, retinoids, tetracyclines, furosemide are examples
	Photoallergy	Usually to topical agents, particularly sunscreens and NSAIDs
Metabolic	Porphyrias	Mainly porphyria cutanea tarda and erythropoietic protoporphyria
	Pellagra	Photo-exposed site dermatitis due to tryptophan deficiency (see Fig. 5.14)
Photogenodermatoses	Xeroderma pigmentosum	Rare. Defect in DNA excision repair, abnormal photosensitivity, photo-ageing and skin cancer. There may be neurological features
Photo-aggravation of pre-existing conditions	Lupus erythematosus Erythema multiforme (p. 1144) Rosacea(p. 1123)	Lupus can also be drug-induced (see Box 26.35)

(HLA = human leucocyte antigen; NSAIDs = non-steroidal anti-inflammatory drugs; UVA/UVB = ultraviolet A/B; UVR = ultraviolet radiation)

Patients with photosensitivity diseases can be abnormally sensitive to UVB, UVA, visible light (> 400 nm) or, commonly, a combination of wavebands. UVB is absorbed by window glass, whereas UVA and visible light are transmitted through glass.

Clinical assessment

Taking a careful history is essential, as the patient may not have the rash when assessed. Seasonal pattern and distribution of rash are important. Key sites are the face (particularly nose, cheeks and forehead), top of ears, neck (Fig. 26.7), bald scalp, back of hands and forearms. Sparing is often seen under the chin and nose, behind the ears, on the upper eyelids and the distal digits. It can be misleading if there is covered site involvement. Patients who are sensitive to UVA and visible light may have perennial symptoms and symptoms triggered with light through clothing and window glass. Sparing of habitually exposed sites, such as the face and back of hands, occurs most commonly in polymorphic light eruption (PLE) and is called the 'hardening phenomenon'. Some conditions, such as solar urticaria, develop rapidly after sunlight exposure, whereas others, such as cutaneous lupus, can take several days or weeks to develop after light exposure.

Investigations and management

If photosensitivity is suspected, the patient should be referred to a specialist centre for assessment and investigation, usually involving monochromator phototesting. Other investigations will often include provocation, patch or photopatch testing and screening for lupus and porphyria. Rarely, investigations such as human leucocyte antigen (HLA) typing in suspected actinic prurigo, or DNA excision repair functional activity or genotyping in suspected xeroderma pigmentosum, may be required.

Management includes removal of any treatable cause, such as a light-sensitising drug and counselling regarding sun protection habits:

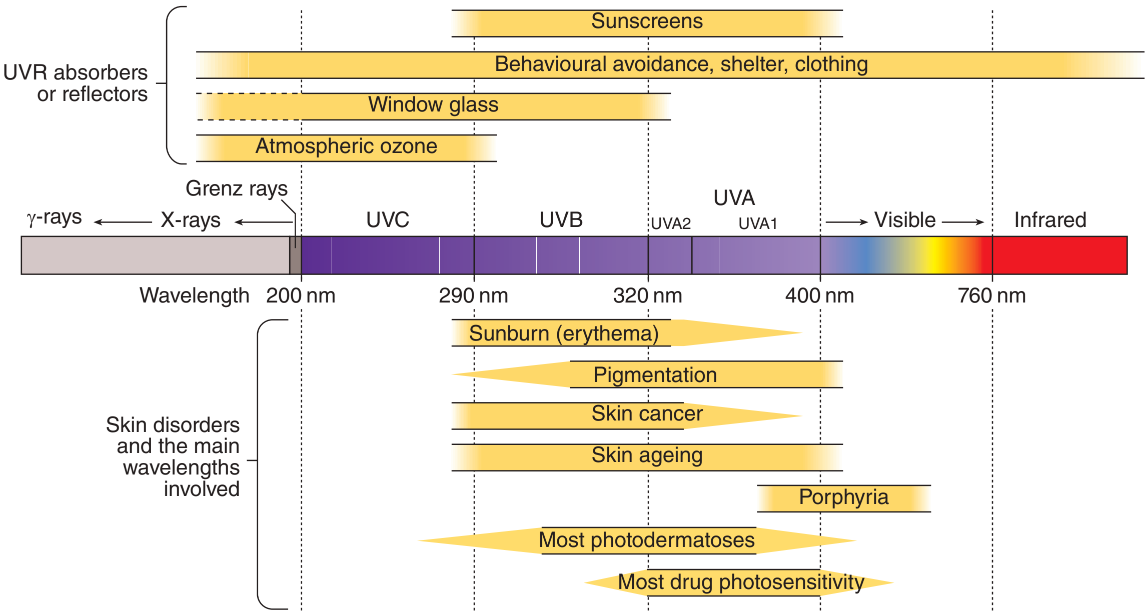

Fig. 26.6 The electromagnetic spectrum. The action spectrum is not well defined for many conditions and, for some, is approximate and may vary between patients. The action spectrum for non-melanoma skin cancer mirrors that for erythema. The action spectrum for melanoma is not known but includes UVA and UVB. Photoprotection measures vary, depending on condition, although the mainstay always includes behavioural modification, clothing cover and appropriate sunscreen choices. (UV = ultraviolet; UVR = ultraviolet radiation)

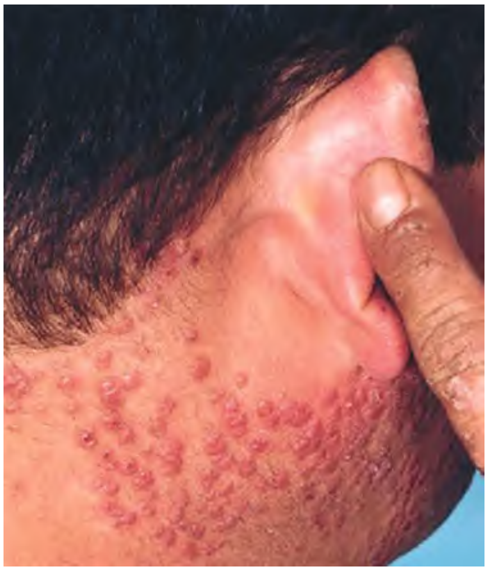

Fig. 26.7 Chronic actinic dermatitis. Note the sharp cut-off and sparing behind the ear in the shadow cast by the earlobe (Wilkinson triangle).

avoidance of sun in the middle of the day, clothing, hats and high-factor sunscreens. Sometimes ‘hardening’, the term used to describe immune tolerance induced by natural light or phototherapy, can be induced. Other approaches depend on the disease and severity, and may include antihistamines, immunosuppressants or biologics, such as omalizumab in solar urticaria. Patients with photosensitivity who photoprotect are at increased risk of vitamin D deficiency and often require supplements.

Sunscreens

Sunscreens can be divided into two categories: chemical sunscreens, which absorb specific wavelengths of UVR, and physical sunscreens, which reflect UVR and the shorter visible wavelengths (see Fig. 26.6). Sunscreens are now highly sophisticated and most offer protection against UVB and most UVA wavelengths. Conventional absorbent sunscreens have limited protection into the visible part of the spectrum and historically were inferior to reflectant sunscreens. However, the latter were less cosmetically acceptable due to visible light reflection, but current sunscreen formulations, some of which are tinted, have reduced this problem.

Sunscreen protection levels are described by sun protection factor (SPF). This is the ratio of the dose of UVR required to produce skin erythema in the presence and absence of the sunscreen. A sunscreen of SPF20 means that it would take 20 times as long for a person to develop sunburn in the presence of the sunscreen, as compared to not using it. Therefore, SPF is a sunburn protection factor and is not a good guide to how well a sunscreen will perform in protecting against photosensitivity diseases. SPF values are determined under experimental conditions whereas, in practice, people tend to use 25%–33% of the amount of sunscreen required to achieve the stated SPF and it is easy to be lulled into a false sense of security of believing that higher levels of sun protection will be achieved than will be the reality. Patient counselling is therefore important for adequate sunscreen application. There is no such thing as a complete ‘sunblock’ as sunscreens offer, at best, partial protection and are no substitute for modifying behaviour and covering up.

Leg ulcers

Leg ulcer is not a diagnosis, but a symptom of an underlying disease in which there is complete epidermal loss, leaving dermal layers exposed. Ulcers on the lower leg are frequently caused by vascular disease but there are other causes, as summarised in Box 26.10.

Clinical assessment

A detailed history of the onset and course of leg ulceration and predisposing conditions should be elicited. The site and surrounding skin should be assessed. Varicose veins are often present, although not inevitably. Assessment of the venous and arterial vasculature and neurological examination are critical. The site of ulceration may also help to indicate the underlying primary cause (Fig. 26.8). Full clinical examination is essential as the ulcer may be arising in the context of systemic disease, such as vasculitis.

i 26.10 Causes of leg ulceration

Venous hypertension

- Sometimes following deep vein thrombosis

Arterial disease

- Atherosclerosis
- Vasculitis
- Buerger disease

Small-vessel disease

- Diabetes mellitus
- Vasculitis

Haematological disorders

- Sickle-cell disorder
- Cryoglobulinaemia
- Spherocytosis
- Polycythaemia
- Myeloma
- Waldenström macroglobulinaemia
- Immune complex disease

Neuropathy

- Diabetes mellitus
- Leprosy (Hansen disease)
- Syphilis

Tumour

- Squamous cell carcinoma
- Basal cell carcinoma
- Malignant melanoma
- Kaposi sarcoma

Trauma

- Injury
- Factitious

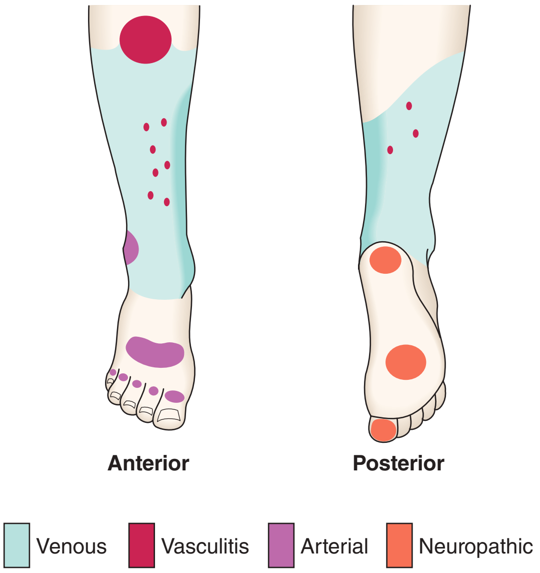

Fig. 26.8 Causes of lower limb ulceration. The main types of leg ulcer tend to affect specific sites.

Leg ulceration due to venous disease

Varicose veins, a history of deep venous thrombosis and obesity are predisposing factors. Incompetent valves in the deep and perforating veins of the lower leg result in retrograde flow of blood to the superficial system, and a rise in capillary pressure ('venous hypertension'). Pericapillary fibrin cuffing occurs, leading to impairment of local tissue oxygenation.

The first symptom in venous ulceration is often heaviness of the legs, followed by oedema. Haemosiderin pigmentation, pallor and firmness of surrounding skin, and sometimes venous/gravitational eczema subsequently develop. This progresses to lipodermatosclerosis – firm induration due to fibrosis of the dermis and subcutis, which may produce the well-known 'inverted champagne bottle' appearance. Ulceration follows, often precipitated by trauma or infection. Venous ulcers typically occur on the medial lower leg (Fig. 26.9).

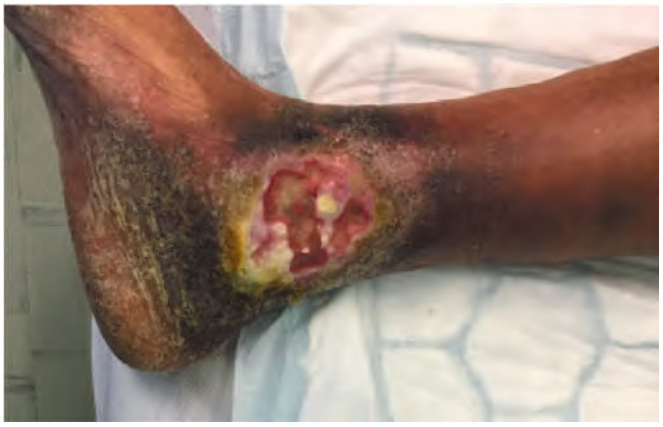

Fig. 26.9 Patient with chronic venous insufficiency who has chronic venous stasis skin changes and venous ulceration. *From Shortell CK, Markovic JN. Venous ulcers. 2nd ed. Elsevier; 2023.*

Complications of venous leg ulceration include bacterial colonisation and infection, and contact allergic dermatitis to topical medicaments, dressings and bandages. Lipodermatosclerosis may cause lymphoedema and hyperkeratosis; rarely, squamous cell carcinoma (SCC) may develop in a long-standing venous ulcer (Marjolin ulcer).

Leg ulceration due to arterial disease

Deep, painful, punched-out ulcers on the lower leg, especially the shin and foot and in the context of intermittent claudication, are likely to be due to arterial disease. Risk factors include smoking, hypertension, diabetes and hyperlipidaemia. The foot is cold and dusky, and the skin atrophic and hairless. Peripheral pulses are absent or reduced. In these circumstances a vascular surgical assessment should be sought urgently.

Leg ulceration due to vasculitis

Vasculitis can cause leg ulceration either directly through epidermal necrosis due to damage to underlying vasculature, or indirectly due to neuropathy.

Leg ulceration due to neuropathy

The most common causes of neuropathic ulcers are diabetes and leprosy. Microangiopathy also contributes to ulceration in diabetes. Ulcers occur over weight-bearing areas, such as the heel. In the presence of neuropathy, protection of skin from trauma is essential to prevent ulceration.

Investigations

Appropriate investigations include:

- *Full blood count* to detect anaemia and blood dyscrasias.
- *Urea and electrolytes* to assess renal function.
- *Urinalysis* for glycosuria.
- *Bacterial swab* if there is a purulent discharge, rapid extension, cellulitis, lymphangitis or sepsis. This can guide antibiotic therapy for secondary infection, but pathogenic bacteria are not always the same as those identified from the ulcer surface.
- *Doppler ultrasound* to assess arterial circulation. An ankle systolic pressure to brachial systolic pressure index (ABPI) of below 0.8 suggests significant arterial disease and a vascular surgery opinion should be sought. However, arterial calcification, such as in diabetes, can produce a spuriously high ABPI. Pulse oximetry may also be useful, although ABPI is the preferred investigation if feasible.

Management

General advice on exercise, weight loss and smoking cessation is important in all cases. Specific management depends on making the correct diagnosis to identify the cause(s) of ulceration. Underlying factors, such as diabetes or anaemia, must be treated. Oedema must be reduced by leg elevation and, if there is no arterial compromise, graduated compression bandaging from toes to knees to enhance venous return and improve healing. Compression bandaging is effective for individuals with an ABPI of more than 0.8 but should be avoided if the ABPI is less than 0.8.

If the ulcer is purulent, weak potassium permanganate soaks may help, and exudate and slough can be removed with normal saline or clean water. Dressings do not themselves heal leg ulcers, but can reduce discomfort and odour and, by reducing colonisation by potential pathogens, may reduce the frequency of secondary infection. A variety of dressings may be used, including non-adherent and absorbent (alginates, hydrogels, hydrocolloids) types. The frequency of dressing changes varies; heavily exudative ulcers may need daily dressings, whereas changes once weekly may suffice for drier ulcers. Occasionally, leeches may be used topically for ulcers with heavy adherent exudate.

Surrounding eczema should be suppressed with a topical glucocorticoid. Commonly, this is venous eczema, but there should be a low threshold for referral for patch testing, as contact allergy to topical applications is common. Systemic antibiotics are indicated only if there is evidence of infection, as opposed to colonisation. Various techniques of split-thickness grafting (such as pinch and mince grafts) may hasten healing of clean ulcers but do not reduce recurrence risk. Leg ulcers can be very persistent but with accurate diagnosis and optimal management, healing is usually achievable. Symptomatic relief, including oral analgesics and sometimes chronic pain management, is important. Once the ulcer has healed, ongoing use of compression hosiery is advised to limit the risk of recurrence.

Abnormal pigmentation

Loss of skin pigmentation (depigmentation), reduction in pigmentation (hypopigmentation) and increased pigment (hyperpigmentation) are features of a variety of disorders. A detailed history and examination, including use of a Wood's light, are required to establish the diagnosis. Investigations will depend on the presentation. For example, microscopy of skin scrapings should be undertaken if hypopigmentation is associated with inflammation and scaling; screening for autoimmune disease may be required if vitiligo is suspected; and investigation for endocrine disease or the porphyrias may be appropriate in hyperpigmentation. Further details of the specific conditions are discussed later in this chapter.

Hair and nail abnormalities

Many conditions affect the skin appendages, particularly hair and nails. Conditions causing hair loss (alopecia) are listed in Box 26.30. Nail changes may be a marker for systemic disease, such as iron deficiency, or be a feature of certain skin conditions, such as psoriasis.

Acute skin failure: erythroderma and epidermal necrolysis

Acute skin failure is a medical emergency, and this broad term includes erythroderma and epidermal necrolysis presentations. Several conditions can cause widespread and acute failure of many skin functions (see Box 26.1), including thermoregulation, fluid balance control and barrier to infection. Many of these conditions involve widespread dilatation of the dermal vasculature and can provoke high-output cardiac failure; they are also associated with increased protein loss from the skin and often from the gut. Many lead to acute skin failure by causing erythroderma (erythema affecting at least 90% of the body surface area), although severe autoimmune blistering diseases and the spectrum of Stevens–Johnson syndrome/toxic epidermal necrolysis (TEN) disease can produce acute skin failure without erythroderma.

Clinical assessment

Detailed history-taking and full examination are required. Particular attention should be paid to drug history, chronology and history of any preceding skin disease. Eczema, psoriasis, drug eruptions and cutaneous T-cell lymphoma (Sézary syndrome) are among the diseases that can either present with, or progress to, erythroderma. Other causes include the psoriasis-like condition pityriasis rubra pilaris, and rare types of ichthyoses. Erythroderma may occur at any age and is associated with severe morbidity and significant mortality (see Fig. 26.36D). Older people are at greatest risk, especially if they have comorbidities. Erythroderma may appear suddenly or evolve slowly. In dark skin, the presence of pigmentation may mask erythema, giving a purplish hue.

Erythrodermic patients are usually systemically unwell with shivering and hypothermia, secondary to excess heat loss. However, they may also be pyrexial and unable to lose heat due to damage to sweat gland function and sweat duct occlusion. Tachycardia and hypotension may be present because of volume depletion. Peripheral oedema is common in erythroderma, owing to low albumin and high-output cardiac failure. Lymph nodes may be enlarged, either as a reaction to skin inflammation or, rarely, due to lymphomatous infiltration. Gastro-intestinal ileus and multi-organ failure may be life-threatening or fatal complications.

Investigations and management

Investigations are required to establish the underlying cause and to identify systemic involvement, such as hypoalbuminaemia, deranged liver and renal function and electrolyte imbalance. Skin biopsy may be necessary if the cause is unclear. Regardless of the cause, important aspects of the management of erythroderma include supportive measures to ensure adequate hydration, maintenance of core temperature and adequate nutrition. Insensible fluid loss can be many litres above normal losses. Protein may be lost directly from the skin and through the gut because of the protein-losing enteropathy that often accompanies conditions such as erythrodermic psoriasis. To reduce the risks of infection, any intravenous cannula should be sited in peripheral veins, if possible. In the initial management of acute erythroderma, urinary catheterisation is often required (for patient comfort and accurate fluid balance monitoring) but catheters should be removed as soon as possible. Frequent application of a simple ointment or spray emollient (such as white soft paraffin/liquid paraffin mix) is usually appropriate.

Principles of management of skin disease

General measures

General measures that apply in all skin diseases include establishment of the correct diagnosis, removal of precipitating or aggravating factors, use of safe, effective treatments and consideration of the patient holistically, considering the impact of the disease on quality of life and the person's support network. The psychological impact of chronic skin diseases should not be under-estimated, and it is important to remember that psychiatric illness can also manifest as skin disease, such as in delusions of infestation or trichotillomania. Careful clinical assessment is essential, and any management strategy must also include approaches to address the psychological well-being of the patient.

Topical treatments

Topical treatments are first-line therapy for most skin diseases, many of which can be treated effectively by topical agents alone. Selection of the appropriate active drug/ingredient and vehicle is essential. Ointments are preferred to creams for dry skin conditions, such as chronic eczemas,

26.11 Characteristics of vehicles used in topical treatments

Vehicle	Definition	Use	Site	Cosmetic acceptability	Risk of contact sensitisation
Creams	Emulsions of oil and water (aqueous cream)	Acute presentations Cooling, soothing Well absorbed Mild emollients	All sites, including mucous membranes and flexures, but not hair-bearing areas	Very good Helps adherence	Significant, due to preservatives, antimicrobials and often lanolin
Ointments	Greasy preparations Insoluble in water (white soft paraffin) Soluble (emulsifying ointment)	Chronic dry skin conditions Occlusive and emollient Hydrating Mildly anti-inflammatory	Avoid hair-bearing areas and flexures	Moderate	Low
Lotions	Water-based Liquid formulation Often antiseptic and astringent (potassium permanganate)	Cooling effect Cleans the skin and removes exudates	Large areas of the skin and the scalp	Good, but can sting if in an alcoholic base	Rare
Gels	Thickened lotions Hydrophilic and hydrophobic bases	For specific sites	Hair-bearing areas and the face	Good	Low
Pastes	Semi-solid preparations consisting of finely powdered solids suspended in an ointment	Occlusive, protective Hydrating Circumscribed skin lesions (psoriasis, lichen simplex chronicus)	Any area of skin Often used in medicated bandages	Moderate	Moderate

as they are more hydrating and contain fewer preservatives than creams, and so allergy risk is reduced. However, patients find creams easier to apply and thus compliance may be better. Gels and lotions can be easier to use on hair-bearing sites. The molecular weight and lipid–water coefficient of a drug determine its skin penetration, with larger, water-soluble, polar molecules penetrating poorly. In skin disease, if the stratum corneum is impaired – as in eczema – increased drug absorption occurs. Occlusion under dressings also increases absorption. Drugs can be used in different potencies or concentrations, or in combination with other active ingredients, and many are available in more than one formulation. The properties of different vehicles are listed in Box 26.11. Overall, adherence to topical treatments can be problematic, so it is essential for patients to know exactly what is required of them and for regimens to be kept as simple as possible. Emollients, topical glucocorticoids and other selected key topical therapies that are widely used in a diverse range of skin conditions are detailed below. For the more disease-specific therapies, detailed descriptions are included in the disease sections.

Emollients

These are mainstays in the treatment of eczema, psoriasis and many other conditions, and are used to moisturise, lubricate, protect and 'soften' skin. They are essentially vehicles without active drug and are available in many formulations: creams, ointments, gels and bath, shower and soap substitutes. White soft paraffin is the most effective and is widely used. Caution is required about the flammable nature of paraffin-based emollients and avoidance of contact with mucosae is advised, as ocular inflammation may occur with some emollients.

Topical glucocorticoids

Glucocorticoids are available in a variety of formulations, potencies and strengths, most commonly as creams and ointments (Box 26.12). Selection of the correct product depends on the condition being treated, body site and duration of expected use. Mild topical glucocorticoids are used in delicate areas, such as the face or genitals, and close supervision of glucocorticoid use at these sites is required. In contrast, very potent glucocorticoids may be required under occlusion for chronic resistant disease, such as nodular prurigo.

26.12 Potencies and strengths of commonly used topical glucocorticoid preparations*

Mild

- Hydrocortisone 0.5%, 1%, 2.5%
- Hydrocortisone 1% and fusidic acid 2% (Fucidin H)

Moderate

- Clobetasone butyrate 0.05% (Eumovate)
- Betamethasone valerate 0.025% (Betnovate-RD; Audavate-RD)
- Fluocinolone acetonide 0.00625% (Synalar 1:4)

Potent

- Betamethasone valerate 0.1% (Betnovate; Audavate)
- Betamethasone valerate 0.1% and clioquinol 3% (Betnovate-C)
- Fluocinolone acetonide 0.025% (Synalar)
- Hydrocortisone butyrate 0.1% (Locoid)
- Mometasone furoate 0.1% (Elocon)

Very potent

- Clobetasol propionate 0.05% (Dermovate)
- Betamethasone dipropionate 0.05% (Diprosone)

*UK proprietary names are given in brackets.

Adverse cutaneous effects of chronic glucocorticoid use include atrophy (definition: an area of thin, translucent skin caused by loss of epidermis, dermis or subcutaneous fat – Fig. 26.10), striae (definition: linear, atrophic, pink, purple or white bands caused by connective tissue changes – Fig. 26.10), petechiae and purpura (definition: haemorrhagic macules or papules caused by extravasated blood) and telangiectasiae (definition: visible dilatations of small cutaneous blood vessels – see Fig. 26.12A), increased risk of infection and systemic absorption, causing Cushingoid features and suppression of the hypothalamic–pituitary–adrenal axis. However, under-treatment with glucocorticoids is more common than over-treatment in routine clinical practice. In general, the lowest potency of glucocorticoid should be used for the shortest period to gain control of the disease; this can be achieved by initial use of a more potent glucocorticoid, with reduction in potency or frequency of application as control is gained. Tolerance or tachyphylaxis can develop with chronic use, so intermittent courses of treatment are advised. Caution is required with glucocorticoids

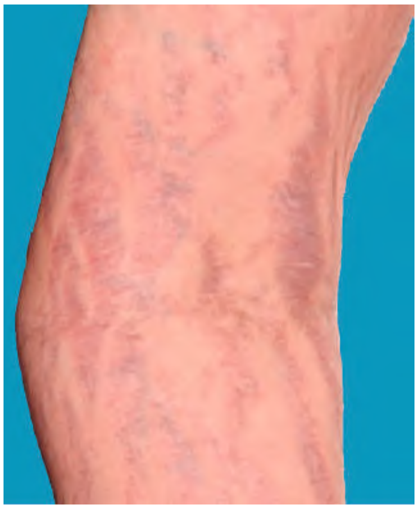

Fig. 26.10 Striae and atrophy induced by excess prolonged potent topical glucocorticoid use.

in psoriasis, as rebound, unstable or pustular psoriasis can occur with sudden cessation of use. Nevertheless, glucocorticoids are invaluable for many sites, particularly the flexures. Topical glucocorticoids are often formulated in combination with antiseptics, antibiotics or antifungals, and their controlled use may be appropriate for short-term use in infected eczema or flexural psoriasis. Intralesional injections of glucocorticoids can be used in a variety of indications, including nodular prurigo, keloid scar (definition of 'scar': replacement of normal structures by fibrous tissue at the site of an injury, although keloid scar describes a pathological process extending beyond the site of injury), acne cysts and alopecia areata.

Anti-infective agents

Antiseptics should be considered before antibiotics, as they cover a wide range of organisms and help to reduce the risk of antibiotic resistance. Antibiotics can be used either for their anti-infective or anti-inflammatory properties. Topical antiviral and antifungal agents are also widely used for a range of mild skin infections.

Calcineurin inhibitors

The topical calcineurin inhibitors tacrolimus and pimecrolimus can be used to treat eczema and a variety of other conditions, through local cutaneous immunosuppression.

Immune response modifiers

Topical imiquimod was introduced for the treatment of anogenital warts but can be used for a diverse range of other skin diseases, including actinic keratosis, Bowen disease, basal cell carcinoma, lentigo maligna, cutaneous lupus and common and planar warts. Its mechanism of action is via stimulation of endogenous Th2 immune responses and release of cytokines, including interferon-gamma (IFN-γ). It can cause significant inflammation, requiring dose adjustments, but subclinical disease may respond to treatment.

Dressings

A 'wound' covering is called a dressing. Box 26.13 shows the indications for their use. The active agent, vehicle and 'wound' type should be considered. Wet lesions should be treated with wet dressings. Paste bandages can be used in conjunction with topical emollients and glucocorticoids to soothe and cool, ease pruritus and scratching, and reduce inflammation. Dressings for venous leg ulcers are described later in this chapter.

i 26.13 Indications for dressings

- Protection
- Symptomatic relief from pain or itch
- Maintenance of direct application of topical treatment
- Possible improvement in healing time
- Reduction of exudate
- Reduction of odour

Phototherapy and photochemotherapy

Ultraviolet radiation (UVR) treatments (most commonly, narrowband ultraviolet B and psoralen–ultraviolet A (PUVA)) are used in the management of many different diseases and are invaluable therapies to have available. The best evidence for their efficacy is in psoriasis, atopic eczema, vitiligo and chronic urticaria, although there is also evidence that UVB is helpful in treating generalised itch associated with chronic kidney disease (uraemic pruritus) and a range of other diverse skin conditions.

Psoralens are natural photosensitisers found in many plants. They intercalate between the strands of DNA and, on excitation with UVA, cross-link the DNA strands. Psoralens are therefore prodrugs that are activated only in skin that is exposed to UVA. Psoralens can also be applied topically in a bath before irradiation with UVA (bath PUVA) or can be applied in creams or gels for localised topical PUVA. PUVA is a more complex treatment than UVB and has more adverse effects; in particular, cumulative exposure to PUVA increases the risk of skin cancer, particularly squamous cell carcinoma. Therefore, PUVA is generally used for poor responders to UVB, or in diseases such as plaque-stage cutaneous T-cell lymphoma or pityriasis rubra pilaris, where it is the phototherapy of first choice. Phototherapy or PUVA may be offered as a whole-body or localised treatment and UVB phototherapy can be available as a home-based treatment.

Longer-wavelength UVA1 (340–400 nm) is also used for several conditions, particularly the fibrosing skin diseases such as morphoea, where efficacy has been shown and there is a lack of other well-proven therapies. The evidence for its place in the management of several diseases, such as eczema, is not fully proven and availability of UVA1 is mainly through tertiary referral centres with expertise in photodermatology and phototherapy.

Systemic therapies

General information is provided here for drugs used in a range of skin diseases; details of other drugs are provided in disease-specific sections.

Antibiotics

Antibiotics are widely used for their anti-infective properties, particularly for staphylococcal and streptococcal skin infections. In these indications, the correct antibiotic should be selected, based on bacterial sensitivity and patient factors. As examples, oral flucloxacillin may be indicated for clinically infected eczema, intravenous flucloxacillin for cellulitis, and clarithromycin for a patient with a staphylococcal carbuncle who is penicillin allergic. Optimal therapeutic doses and courses must be chosen, based on local antimicrobial prescribing guidelines. Several antibiotics, such as tetracyclines, erythromycin and co-trimoxazole, are used predominantly for their anti-inflammatory effects in indications such as acne vulgaris, bullous pemphigoid and pyoderma gangrenosum.

Antihistamines

A range of H_1- and H_2-receptor antagonists are used in dermatology. For diseases in which histamine in the skin is relevant (such as urticaria), non-sedating antihistamines should be used, for example, fexofenadine or cetirizine. For pruritic conditions such as eczema, the sedating effect of antihistamines like hydroxyzine or chlorphenamine is important. However, antihistamines are widely used in older patients for the symptom of pruritus due to a variety of causes such as xeroderma, metabolic impairment, malignancy or concomitant drugs. Sedating antihistamines should be used with caution in older patients, as they may increase the risk of falls and accidents in the home, with disastrous consequences. Careful choice of drug and dose is therefore essential. Leukotriene receptor antagonists may be considered in addition to antihistamine regimens, for additional mast cell stabilising effects.

Retinoids

Oral retinoids are used in a range of conditions, including acne, psoriasis and other keratinisation disorders. They promote differentiation of skin cells and have anti-inflammatory effects. Isotretinoin (13-*cis*-retinoic acid) is widely used for moderate to severe acne. Acitretin can be effective in psoriasis and other keratinisation disorders, such as ichthyosis, as can alitretinoin (9-*cis*-retinoic acid) in hand and foot eczema and bexarotene in cutaneous T-cell lymphoma.

Adverse effects of retinoids include dryness of the skin and mucous membranes, abnormalities in liver function or hepatitis, increase in serum triglycerides (levels should be checked before and during therapy) and potentially mood disturbance. Alitretinoin and bexarotene can cause hypothyroidism. Systemic retinoids are teratogenic and must be prescribed along with a robust form of contraception. Females must have a negative pregnancy test before, during and after therapy, and pregnancy must be avoided for 2 months after stopping isotretinoin and 2 years after stopping acitretin.

Immunosuppressants

Systemic glucocorticoids, particularly prednisolone, are widely used in inflammatory skin diseases, such as eczema, immunobullous disease and connective tissue disorders. Methotrexate, azathioprine and mycophenolate mofetil are effective in eczema and psoriasis, either alone or as glucocorticoid-sparing agents. Further details on the mechanism of action, adverse effects and monitoring requirements for these agents are provided in Chapter 25 (see Box 25.33). Hydroxycarbamide is an alternative immunosuppressant to methotrexate in psoriasis but is not licensed for this indication and appears to be less effective than methotrexate. The risk of myelosuppression is greater. Mycophenolate mofetil is an alternative to consider. Dimethyl fumarate may be used off label in the treatment of psoriasis. Ciclosporin has a rapid onset of action and is effective in inducing clearance of psoriasis and eczema. Monitoring of blood pressure and renal function is required. Ciclosporin should be used only with caution after phototherapy, and should be avoided after PUVA, because of the increased risk of skin cancer. Long-term use of ciclosporin is not advised. Dapsone is an immunomodulator and may be used in diseases in which neutrophils are implicated, such as dermatitis herpetiformis. Haemolysis, methaemoglobinaemia and hypersensitivity can occur, and monitoring is required. Hydroxychloroquine is of particular value in cutaneous lupus, but caution and monitoring are required with respect to cumulative risk of retinal toxicity.

Biologic and targeted immunosuppressives/modulators

Major advances in the treatment of inflammatory skin diseases have been made in recent years through increased understanding of pathophysiology, the identification of new molecular targets for drug design and the introduction of biological treatments and small molecules that target specific signalling pathways involved in the inflammatory response. Biologic treatments work by binding to and neutralising pro-inflammatory cytokines or components of their receptors whereas small molecule inhibitors target intracellular signalling pathways situated downstream of cytokine receptors.

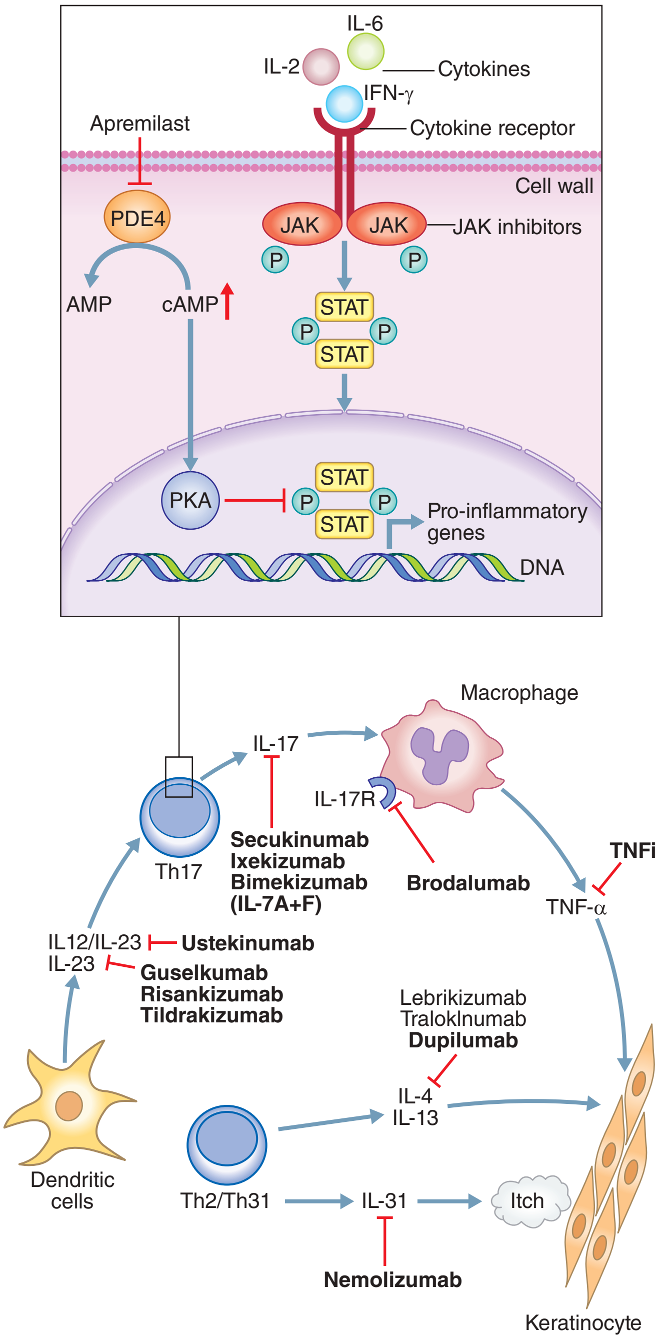

Fig. 26.11 Biologic and targeted therapies in inflammatory skin diseases. Biologic treatments for inflammatory skin diseases work by targeting key cytokines or their receptors involved in regulating the immune response. (cAMP = cyclic adenosine monophosphate; IL = interleukin; JAK = Janus activated kinase; PKA = protein kinase A; PDE4 = phosphodiesterase E4; STAT = signal transducers and activators of transcription; Th = T-helper cell subtype; TNF-α = tumour necrosis factor alpha; TNFi = inhibitor of tumour necrosis factor alpha)

Multiple biologics are available for the treatment of severe or conventional treatment-resistant psoriasis. These include multiple inhibitors of tumour necrosis factor alpha (TNF-α) (adalimumab, certolizumab, etanercept and infliximab); ustekinumab, which inhibits interleukin (IL)-12 and IL-23 by binding to the p40 component of both cytokines; guselkumab, risankizumab and tildrakizumab, which are specific inhibitors of IL-23; ixekizumab, secukinumab and bimekizumab, which are inhibitors of IL-17, the latter inhibiting IL-17A and IL-17F; and brodalumab, which inhibits the IL-17 receptor (Fig. 26.11).

Dupilumab is an antibody that targets the IL-4 receptor alpha chain subunit, which is common to both IL-4 and IL-13 receptors and is effective in the treatment of severe atopic dermatitis resistant to standard therapies. Tralokinumab and lebrikizumab are specific inhibitors of IL-13, also effective in the treatment of severe atopic dermatitis. Dupilumab and tralokinumab are approved for use in atopic eczema; lebrikizumab is approved for use in moderate to severe atopic dermatitis. Omalizumab, a monoclonal antibody directed against immunoglobulin E (IgE), which is used in severe asthma, also has a role in the treatment of urticaria and some patients with atopic dermatitis.

Small molecule targeted synthetic immunosuppressives have also been developed. Apremilast inhibits phosphodiesterase-E4 (PDE4) reducing cytokine production by immune cells and is used in psoriasis. Crisaborole is a topical PDE4 inhibitor for the treatment of atopic eczema, although it is not available in Europe. The development of Janus activated kinase (JAK) inhibitors has exploded, with exciting developments for use in atopic dermatitis, psoriasis, vitiligo and alopecia areata. Baricitinib, upadacitinib, tofacitinib and abrocitinib are effective in psoriasis and atopic dermatitis. Topical ruxolitinib has been shown to have efficacy in vitiligo, and baricitinib, ritlecitinib and deuruxolitinib show promise for patients with alopecia areata, for whom other effective options are extremely limited. Rituximab, which binds to CD20 causing depletion of B cells, is used in pemphigus vulgaris. Intravenous immunoglobulin, pooled from donor plasma, may be used in the treatment of dermatomyositis and occasionally may be indicated in other dermatological diseases, although may be difficult to access. More detail on the dosages, mechanism of action and adverse effects of these agents are provided in Chapter 25 (see Box 25.35).

Other therapeutic targets under investigation are IL-31: nemolizumab blocks the IL-31 receptor and has reported efficacy in atopic dermatitis itch and nodular prurigo; IL-36: spesolimab and imsidolimab are IL-36 inhibitors showing great promise for generalised pustular psoriasis; fingolimod, which targets the sphingosine-1-phosphate pathway, which is involved in trafficking immune cells into the skin; fezakinumab, which inhibits IL-22, a pro-inflammatory cytokine implicated in the pathogenesis of psoriasis and atopic dermatitis; and tapinarof, a small molecule modulator of the aryl hydrocarbon receptor, which is a transcription factor involved in regulating production of IL-17 and other cytokines in the skin. Tumour targeted kinase inhibitors and biologics directed against CTLA-4 and the programmed cell death (PD-1) pathways, which are used in the treatment of melanoma, are discussed later in this chapter.

Dermatological surgery

Most dermatological surgical procedures are performed under local anaesthetic. Knowledge of local anatomy is essential, particularly the locations of vessels and nerves. In certain sites, such as the fingers, soles of the feet and the nose, local cutaneous nerve blocks are useful. Some sites are associated with particular risks, such as keloidal scarring on the upper trunk of young patients, unsightly scars over the scapulae, and poor healing and risk of ulceration following procedures on the lower legs.

Excision biopsy

This involves surgical removal of the lesion followed by histological examination. The most common indication is suspicion of malignancy. The lesion and line of excision should be marked out and the margin of excision decided before the procedure. It is important to excise down to the appropriate anatomical plane. Depending on body site, a range of procedures can minimise the resulting defect. Healing by secondary intention may also achieve good cosmetic results.

Curettage

Curettage involves using a small, spoon-shaped implement (curette), not only as a definitive treatment but also to obtain histology. Curettage does not preserve tissue architecture very well, however, and it may be difficult to distinguish between dysplasia and invasive malignancy. It can be an effective treatment for basal cell papilloma (seborrhoeic keratosis), actinic keratosis, intra-epidermal carcinoma and superficial basal cell carcinoma.

Shave excision

Shave excision using local anaesthetic may be used for simple and effective treatment of raised superficial benign skin lesions affecting epidermis and upper dermis, such as benign naevi and skin tags.

Mohs micrographic surgery

Mohs micrographic surgery is employed to ensure adequate tumour excision margins, while conserving unaffected tissue. It is predominantly used for basal cell carcinoma.

Non-surgical treatments

Cryotherapy

Cryotherapy is a destructive treatment using liquid nitrogen to cause cell-wall and membrane destruction and cell death. Liquid nitrogen can be applied either with a cotton bud or, more effectively, with a spray gun. A wide variety of conditions can be treated but it is essential for the correct diagnosis to be made first, if necessary, by diagnostic biopsy. Cryotherapy should not be used to treat melanocytic naevi. Benign lesions, such as viral warts and basal cell papilloma, respond well, and cryotherapy can also be effective for actinic keratosis, Bowen disease or superficial non-melanoma skin cancer. Malignant indications require more vigorous treatment, usually with two cycles, and this is normally carried out in secondary care. Considerable inflammation, blistering and pigmentary change, particularly hypopigmentation, can occur. Caution is required to avoid damage to tendons and nerves, especially when using cryotherapy on digits.

Laser therapy

Laser therapy involves treatment with monochromatic light. Skin components (chromophores), such as haemoglobin and melanin, absorb specific wavelengths of electromagnetic radiation, and these wavelengths can therefore be used to destroy these targets selectively and to treat certain skin disorders. Lasers targeting haemoglobin are employed for vascular abnormalities, such as spider naevi, telangiectasiae and port-wine stains, and lasers targeting melanin can treat benign pigmentary disorders or pigment in tattoos or drug-induced hyperpigmentation. Melanin-targeted lasers can also be used for hair removal if the hair is pigmented. Light delivery in short pulses restricts damage to the treated site.

The carbon dioxide laser emits infrared light that is absorbed by water in tissues and can therefore be used for destructive purposes. The depth of effect can be controlled, such that the carbon dioxide laser is widely employed for resurfacing in photorejuvenation or acne scarring. Significant morbidity is associated with this destructive laser, although this may be minimised with fractionated regimens, and general anaesthesia may be required.

Photodynamic therapy

Photodynamic therapy (PDT) is widely used in dermatology, predominantly for actinic keratoses, Bowen disease and superficial basal cell carcinoma.

Radiotherapy and grenz (Bucky) ray therapy

Radiotherapy can be employed for several skin conditions, including non-melanoma skin cancer or lentigo maligna that is not suitable for surgical treatment, but its use in dermatology has declined. Scarring and poikiloderma can occur at treated sites, although these are minimised if fractionated regimens are chosen. Superficial radiotherapy is now rarely employed to treat benign dermatoses. Even more superficial ionising radiation (grenz (Bucky) rays) can be useful for localised dermatoses that are having severe effects on quality of life, if conventional treatments have been inadequate; for example, it may avoid the need for systemic immunosuppression in a patient with severe recalcitrant localised scalp psoriasis. However, grenz ray therapy is not widely available.

Skin tumours

Pathogenesis

Skin cancer is the most common malignancy in light-skinned populations. It is subdivided into non-melanoma skin cancer (NMSC) and melanoma. NMSC is further subdivided into the most common skin cancer, basal cell carcinoma (BCC), and squamous cell carcinoma (SCC). The latter has precursor non-invasive states of intra-epithelial carcinoma (Bowen disease, BD) and dysplasia (actinic keratosis, AK). Melanoma is much less common than NMSC, but because of its metastatic risk it is the cause of most skin cancer deaths.

UVR is a complete carcinogen and is the main environmental risk factor for skin cancer, which is much more common in countries with high ambient sun exposure, such as Australia. Skin cancer risk also increases if an individual migrates to such a country when young, particularly if less than 10 years of age. Epidemiological evidence supports a close link between chronic UVR exposure and risk of SCC and AK, and a modest link between sun exposure and BCC risk. Melanoma usually arises on sites that are intermittently exposed to UVR, and episodes of sunburn and recreational sun exposure have been implicated as risk factors for melanoma. There is good evidence to show that sunbed exposure is also a risk for both melanoma and NMSC, particularly when exposure starts in adolescence and early adult life. Strategies to reduce sun exposure are therefore important for skin cancer prevention, with reliance mainly on behavioural modification, covering up and judicious sunscreen use. Indeed, there is evidence to show that sunscreen use reduces naevi development in children, and regular sunscreen use in adults reduces the risk of AK and SCC and is likely also to have preventative roles in melanoma and BCC development.

There are identifiable genetic predispositions for some skin cancers, such as in xeroderma pigmentosum, an autosomal recessive condition caused by an inherited defect in DNA excision repair, and basal cell naevus (Gorlin) syndrome, an autosomal dominant disorder caused by loss-of-function mutations affecting the *PTCH1* tumour suppressor genes, with consequent activation of the Hedgehog pathway. Interestingly, the Hedgehog pathway is also almost invariably activated in sporadic BCCs, which usually contain somatic mutations in *PTCH1* and less commonly in the *SMO* gene, which lies in the same signalling pathway. The genetics of SCC are heterogeneous and less clearly defined, with several mutations and pathways implicated, including *TP53*, *CDKN2A/p16*, NOTCH, EGFR and the MAPK signalling pathways. Interestingly, many of the mutations seen in SCC also occur in the pre-cancers AK and BD. The genetics of melanoma are discussed later in this chapter.

Cutaneous immune surveillance is also critical and immunosuppressed organ transplant recipients have a greatly increased risk of skin cancer, particularly SCC. Interestingly, patients who have received high treatment numbers of PUVA (more than 150), which is immunosuppressive, are also at increased risk of skin cancer, particularly SCC.

Although UVB is a complete carcinogen, there is no compelling evidence to date that UVB phototherapy significantly increases skin cancer risk. Likewise, there is no evidence that UVA1 phototherapy increases skin cancer risk, although ongoing vigilance is required. Ionising radiation, notably radiotherapy, thermal radiation and chemical carcinogens, such as arsenic or coal tar, can increase NMSC risk, particularly SCC. A role for oncogenic human papillomaviruses in SCC development is also implicated, particularly in immunosuppressed patients, where viral DNA is detected in more than 80% of tumours. Chronic inflammation is a risk factor for SCC, which may arise in chronic skin ulcers, discoid lupus erythematosus or vulgaris, and the scarring genetic skin disease dystrophic epidermolysis bullosa (see Box 26.25), in which up to 50% of patients develop SCC.

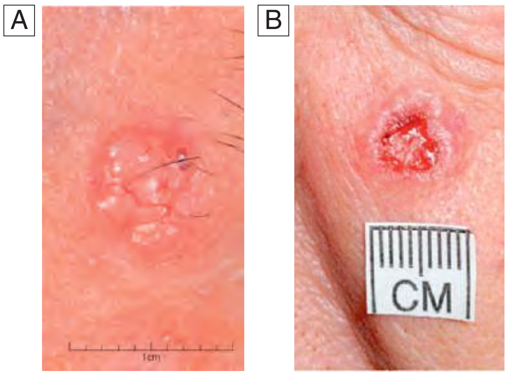

Fig. 26.12 Basal cell carcinoma. **A** A nodular BCC showing the translucent nature of the tumour and the abnormal arborising vessels. **B** An ulcerated BCC showing the raised, rolled edge.

Malignant tumours

Basal cell carcinoma

The incidence of NMSC has increased dramatically in recent decades and basal cell carcinoma (BCC) accounts for more than 70% of cases. In Europe, the ratio of BCC to SCC is 4–5:1 in immunocompetent patients. It is a malignant tumour that rarely metastasises; it is thought to derive from immature pluripotent epidermal cells and is composed of cells with similarities to basal layer epidermis and appendages. Lesions typically occur at sites of moderate sun exposure, particularly the face, and grow slowly. BCC usually occurs in light-skinned people and the incidence increases with age and males are more commonly affected. Lesions may ulcerate and invade locally, hence the term 'rodent ulcer'.

Clinical features

Early BCCs usually present as pale, translucent papules or nodules, with overlying superficial telangiectatic vessels (nodular BCC). If untreated, they increase in size and ulcerate, to form a crater with a rolled, pearled edge and telangiectatic vessels (Fig. 26.12). There may be some pigmentation or a cystic component. A superficial multifocal type can occur, frequently on the trunk, and may be large (up to 10 cm in diameter); often there are multiple lesions. Superficial BCC usually presents as a red/brown plaque or patch with a raised, thread-like edge, which is often best seen by stretching the skin; this helps to distinguish it from Bowen disease. Less commonly, a morphoeic, infiltrative BCC presents as a poorly defined, slowly enlarging, sclerotic yellow/grey plaque.

Diagnosis and management

The diagnosis is often obvious clinically, based on the features mentioned above, although a diagnostic confirmatory biopsy may be required prior to definitive treatment. Management depends on the characteristics of the tumour and on patient factors, including comorbidities and patient wishes. Essentially, treatment will be either surgical or, in some cases, medical (Box 26.14). Surgical excision, ideally with a 4–5 mm margin, is the treatment of choice, with a cure rate of approximately 95%. Curettage and cautery may also be effective for selected lesions. Management of infiltrative morphoeic BCC and/or lesions at difficult sites, such as around the eye, may require more complex techniques, such as Mohs micrographic surgery, to ensure adequate tumour excision margins, while conserving unaffected tissue. This involves processing of frozen sections of all margins in stages (usually on the same day) until all the tumour is removed. The procedure is time-consuming (so can be difficult for older, frail patients) and requires specific surgical and pathology skills, but it is associated with the highest long-term cure rates, with 98%–99% clear at 5-year follow-up.

26.14 Management of non-melanoma skin cancer and pre-cancer

Basal cell carcinoma

- Excision results in the lowest recurrence rates
- Mohs micrographic surgery is effective for high-risk BCC
- Medical treatments are often appropriate for low-risk superficial tumours in patients with comorbidities
- Cryotherapy and topical 5-fluorouracil can be used for superficial BCC
- Topical photodynamic therapy and topical imiquimod are both effective in superficial BCC
- BCC in patients with Gorlin syndrome should not be treated with radiotherapy
- Hedgehog pathway inhibitors can induce clinical response in patients with advanced inoperable BCC
- The checkpoint inhibitor cemiplimab may also be considered in Hedgehog pathway inhibitor-resistant advanced disease

Squamous cell carcinoma

- Excision is the treatment of choice for invasive SCC
- Most recurrences or metastases occur within 5 years
- Medical management is not usually considered for invasive SCC
- Chemotherapy and targeted immunotherapy, notably cemiplimab may be considered in metastatic disease

Carcinoma in situ (Bowen disease)

- For single/few lesions on good healing sites, cryotherapy, curettage, photodynamic therapy, topical imiquimod, 5-fluorouracil or tirbanibulin are options
- For multiple lesions and/or poor healing sites such as the lower leg, photodynamic therapy, where feasible, is the treatment of choice, although topical 5-fluorouracil or imiquimod are alternative treatments

Actinic keratosis

- For single/few lesions on good healing sites, cryotherapy, curettage and 5-fluorouracil + salicylic acid are options, especially if hyperkeratotic
- For multiple lesions/field change, topical 5-fluorouracil, conventional or daylight photodynamic therapy, imiquimod or diclofenac in hyaluronic acid gel may be effective

If a surgical approach is used for management of BCC and the primary tumour is not completely excised, re-excision may be required, although follow-up may be appropriate as not all tumours that are incompletely excised recur. However, this is not recommended for tumours at high-risk sites or for infiltrative morphoeic BCC, where complete excision is advisable. Cryotherapy may be effective for BCC but can cause blistering and scarring, so is best suited to small, superficial lesions at low-risk sites.

Radiotherapy can be invaluable for large BCC lesions in frail patients but is less commonly used because of the risk of scarring.

Medical therapies can be used to treat low-risk BCC, particularly when surgery is not appropriate for a patient. Topical immunomodulators, such as imiquimod, are effective for low-risk BCC and may be particularly useful for patients who are not able to attend a hospital clinic setting but are able to apply a topical preparation at home over a 6-week period. Imiquimod usually induces a prominent inflammatory reaction, and patients should be advised that dose adjustments may be required. Topical 5-fluorouracil can also be effective for low-risk small lesions of superficial BCC, although this usually provokes an intense inflammatory reaction. Intralesional interferon-alfa2b has rarely been used for BCC but multiple treatments and high cost preclude its regular use.

PDT is an effective treatment for low-risk, predominantly superficial BCC, as well as AK and BD. Usually, topical porphyrin PDT is employed, which involves application of a porphyrin prodrug to the lesion to be treated. The prodrug is taken up and converted by the cell's haem cycle to protoporphyrin IX, a photosensitiser. This is photochemically activated by visible (normally red) light, usually delivered by a light-emitting diode (LED), in the presence of oxygen, causing the production of reactive oxygen species, which cause destruction of treated tissue. The photosensitiser is taken up preferentially by diseased skin, and adverse effects in normal skin are minimised. PDT is at least as effective as cryotherapy and surgery for superficial BCC and may be preferred at sites of poor healing, such as the lower leg, or where cosmetic outcome is important. PDT is not as effective as surgery for long-term clearance of nodular BCC but can be considered if surgery is not appropriate. Pain during irradiation may occur during PDT, although adjustments to the irradiation regime can reduce discomfort and treatment is usually well tolerated. PDT is typically undertaken in the out-patient clinic setting and is well suited to frail patients and those unable to undertake treatment with topical agents at home.

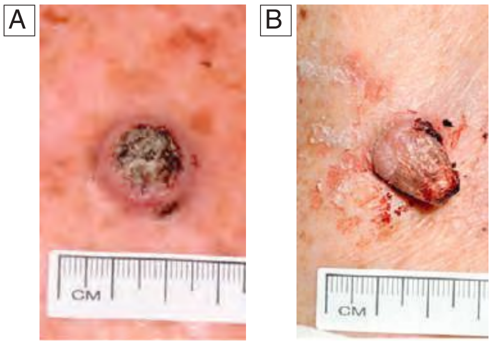

Fig. 26.13 **Squamous cell carcinoma.** **A** A centrally keratinous, symmetrical, well-differentiated SCC. Clinically, this could be confused with keratoacanthoma. **B** An SCC arising from an area of epidermal dysplasia.

Rarely, advanced BCC may be locally invasive or even metastasise. Major advances have been made in targeted drug development, and Hedgehog pathway inhibitors, such as vismodegib and sonidegib, can be used effectively for disease control and palliation in this setting, although there may be significant associated drug-induced toxicity. Additionally, the immune checkpoint inhibitor, cemiplimab, was approved in 2021 for patients with advanced BCC who had failed to respond to/or tolerate Hedgehog pathway inhibitors.

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignancy that arises from epidermal keratinocytes and is the second most common skin cancer, occurring most frequently in older adult males and smokers. There is a close association between cumulative UVR exposure and SCC risk, with most SCC lesions occurring on chronically sun-exposed sites in light-skinned populations and often arising at sites of field-change carcinogenesis, with coexistent precursors of AK and BD commonly evident. In the immunosuppressed patient population, such as organ transplant recipients, SCC is the most common skin cancer and its incidence is dramatically increased, particularly in association with the duration of immunosuppression and the degree of sun exposure and damage accrued pre-transplant. The risk of SCC is also increased in HIV infection. Furthermore, SCC arising in the immunosuppressed is more likely to behave aggressively or to metastasise.

Clinical features

Squamous cell carcinoma usually occurs on chronically sun-exposed sites, such as bald scalp, tops of ears, face and back of hands. The clinical presentation may be diverse, ranging from rapid development of a painful keratotic nodule in a pre-existing area of dysplasia (Fig. 26.13) to the de novo presentation of an erythematous, infiltrated, often-warty nodule or plaque that may ulcerate. The clinical appearance depends on histological grading; well-differentiated tumours more often present as defined keratotic nodules (Fig. 26.13A), whereas poorly differentiated tumours tend to be ill-defined and infiltrative and may ulcerate. SCC has metastatic potential; some tumours, such as those on lips and ears and in immunosuppressed patients, behave more aggressively and are more likely to metastasise to draining lymph nodes.

Management

Early diagnosis is important and complete surgical excision is the usual treatment of choice (see Box 26.14). Standard excision with a 4–6 mm margin is advised, and the cure rate is approximately 90%–95%. Mohs surgery may be a useful option for SCC in critical anatomical sites but is used less frequently for SCC than for BCC. High-risk SCC should be treated aggressively, with a wider margin of excision of at least 6 mm where feasible. This may include larger, thicker lesions, tumours at sites where metastases are more likely, such as the ear, lip or non-sun-exposed sites, and those occurring in the immunosuppressed and/or with histology showing the tumour to be poorly differentiated, with evidence of lymphatic, vascular or perineural involvement or a high mitotic index. Such patients, and those with metastatic disease, require management via a multidisciplinary team as radiotherapy, chemotherapy, targeted therapy or immunotherapy may be considered, particularly in metastatic disease, with cemiplimab, pembrolizumab and cosibelimab as possible approaches in advanced disease. In patients who are at high risk for further SCC, systemic retinoids may have a role in reducing the rate of SCC development, but rapid appearance of tumours may occur on drug cessation. Occasionally, curettage and cautery may be appropriate if the tumour is small and low-risk and either surgical excision is contraindicated, or the patient is unwilling to proceed with excision. Radiotherapy may be indicated if surgical excision is not feasible. Cryotherapy and topical non-surgical therapies are not usually used in invasive SCC because of risk of recurrence and metastasis.

Actinic keratosis

Actinic keratoses (AK) are scaly, erythematous lesions arising on chronically sun-exposed sites. Histology shows dysplasia, although the diagnosis of typical AK is usually made on clinical grounds (Fig. 26.14). They are common in fair-skinned people who have had significant sun exposure, are often multiple and increase with age. The prevalence is much higher in Australia than in the UK and some surveys have shown a prevalence of more than 50% in those over 40 years old. The rate of progression to SCC is less than 0.1% and spontaneous resolution is possible. However, SCC can also arise de novo and without progression from AK. Increase in size, ulceration, bleeding, pain or tenderness can be indicative of transformation into SCC.

Management

Several treatments are available for AK (see Box 26.14). Emollients and photoprotection, including high-factor sunscreens, may suffice for mild disease. Single or low numbers of lesions of AK can be effectively treated with cryotherapy. Hyperkeratotic lesions may be treated with the antimetabolite 5-fluorouracil, combined with salicylic acid, or may require curettage and cautery.

Multiple lesions require field-directed therapy; 5-fluorouracil is widely used in this setting as an effective initial therapeutic approach and topical imiquimod, or occasionally topical tirbanibulin, are alternatives. Diclofenac in a hyaluronic acid gel base can also be used topically for low-grade maintenance control of AK, the rationale for its use being the over-expression of cyclo-oxygenase (COX)-2 in AK lesions. PDT is widely used for field-change multiple AK, with high efficacy rates; it is at least as effective as cryotherapy or 5-fluorouracil. The relative selectivity of treatment allows subclinical disease to be treated, while sparing normal skin. A regimen using daylight to activate the photosensitiser is increasingly and widely used for extensive mild AK, with high efficacy rates, comparable to hospital-based PDT but without the need for specialised equipment and allowing patients to be treated at home.

Bowen disease

Clinical features

Bowen disease (BD) is the name given to an intra-epidermal carcinoma that usually presents as a slowly enlarging, erythematous, scaly plaque on the lower legs of fair-skinned older women (Fig. 26.15) but other sites can also be involved. It can be confused with eczema or psoriasis but is usually asymptomatic and does not respond to topical glucocorticoids. It may also be hard to distinguish from superficial BCC. Transformation into SCC occurs in 3% or less.

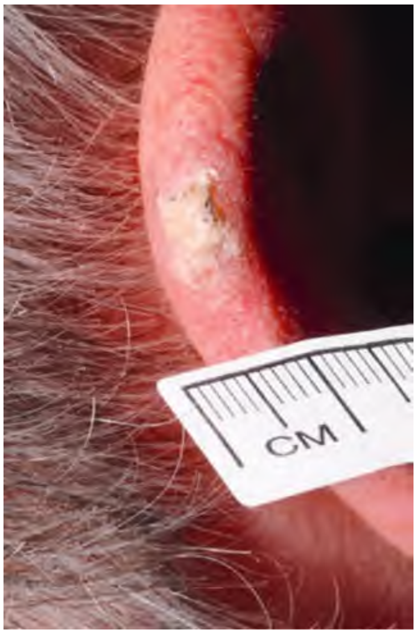

Fig. 26.14 **Actinic keratosis.** Close-up of a hyperkeratotic AK on the ear.

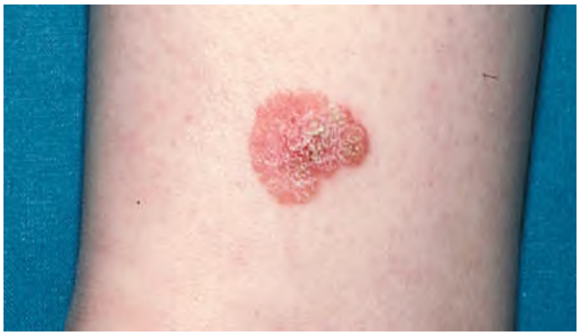

Fig. 26.15 **Intra-epidermal carcinoma (Bowen disease).** The lower leg is a common site, and lesions are often treated non-surgically.

Diagnosis

Incisional biopsy is usually undertaken to confirm the diagnosis. This shows an intra-epidermal carcinoma with no invasion through the basement membrane. Histology may also be obtained by curettage, but this does not allow distinction from invasive SCC to be made, due to loss of tissue orientation and architecture.

Management

While curettage or excision may be appropriate in some settings, non-surgical therapies are generally preferred (see Box 26.14), especially on the lower legs. In particular, PDT may be advantageous for BD on the lower leg because of relative selectivity of treatment and sparing of normal tissue, thus reducing the risk of poor healing and ulceration at this vulnerable site. Given the low risk of malignant transformation, the option of no active treatment may also be appropriate for some frail patients with multiple comorbidities.

Cutaneous lymphomas

The most common form of cutaneous T-cell lymphoma is mycosis fungoides (MF). This can persist for years in patch and plaque stages, often resembling eczema or psoriasis. Only sometimes does it progress through to nodules and finally a systemic stage, Sézary syndrome. B-cell lymphomas, on the other hand, usually present as nodules or plaque-like tumours. The diagnosis of cutaneous T-cell lymphoma requires a high index of suspicion, particularly in patients thought to have unusual recalcitrant forms of eczema or psoriasis.

Treatment is symptomatic and there is no evidence that it alters prognosis. In the early stages of cutaneous T-cell lymphoma, systemic or local glucocorticoids may be indicated; chlormethine gel is useful for localised disease; alternatively, narrowband UVB phototherapy (for patch-stage MF) or PUVA (for plaque-stage MF) may be used. Once lesions have moved beyond plaque stage, localised radiotherapy, electron beam radiation, the synthetic retinoid bexarotene, pegylated interferon-alfa 2A, extracorporeal photopheresis and systemic anti-lymphoma chemotherapy regimens may be needed. Management of advanced disease invariably requires a multidisciplinary team (MDT) approach, with collaboration between dermatologists, pathologists and haematological oncologists. Treatment options for advanced disease are widening with immunomodulatory drugs such as mogamulizumab, brentuximab vedotin and lacutamab, emphasising the importance of the MDT approach.

Melanoma

Melanoma is a malignant tumour of epidermal melanocytes. While only 4% of skin cancers are melanomas, they account for 80% of skin cancer deaths. There has been a steady rise in the incidence of melanoma in light-skinned populations over recent decades, with the highest incidence in Australasia. Primary prevention and early detection are essential, as therapy for advanced and metastatic disease, whilst being a rapidly evolving field, remains challenging.

Pathophysiology

Risk factors for melanoma include light skin tone, freckles, red hair, number of naevi and sunlight exposure. The type of sunlight exposure is under debate but intermittent exposure, such as recreational time in the sun, sunburn and sunbed use, is implicated. Patients with multiple atypical naevi (dysplastic naevus syndrome) and fair-skinned people, often with variant alleles in the melanocortin-1 gene, are at increased risk of melanoma. A family history of melanoma increases the risk, but a strong family history is unusual. Rarely, autosomal dominant inheritance of melanoma with incomplete penetrance can occur due to mutations in *CDKN2A*, which encodes the p16 tumour suppressor protein. In these patients, the lifetime risk of melanoma is more than 50%. Several other susceptibility genes and potential genetic targets for therapeutic intervention in advanced disease have also been identified.

Clinical features

Melanoma can occur at any age and site and in either sex but typically affects the leg in females and back in males. It is rare before puberty. The classification of invasive malignant melanoma is shown in Box 26.15. Early lesions may be in situ and pre-invasive before becoming invasive melanoma with metastatic potential. Any change in naevi or development of new lesions should be assessed to exclude malignancy and examination using a dermatoscope is invaluable (see Fig. 26.2). Real-time non-invasive imaging techniques and artificial intelligence are being investigated as tools to assist in diagnosis but are largely experimental at present. If there is any doubt, excision is advised.

26.15 Classification of cutaneous malignant melanoma

- Melanoma in situ
- Superficial spreading melanoma
- Nodular melanoma
- Lentigo maligna
- Acral lentiginous melanoma
- Subungual melanoma
- Lentigo maligna melanoma

Superficial spreading melanoma

Superficial spreading melanoma (SSM) is the most common type in light-skinned populations. It usually presents as a slowly enlarging, macular, pigmented lesion, with increasing irregularity in shape and pigment; this superficial, radial growth phase can last for approximately 2 years. Subsequently, the lesion may become palpable, and this is indicative of a vertical growth phase, with dermal invasion; when this occurs, the tumour has the potential to invade lymphatics and vessels and to become metastatic (Fig. 26.16A). Approximately 50% of melanomas arise from a pre-existing naevus.

Nodular melanoma

Nodular melanoma is most common in the fifth and sixth decades, particularly in men and on the trunk (Fig. 26.16B). This may account in part for the increased mortality rates from melanoma in men, as these are tumours with greater metastatic risk. They often present as a rapidly growing nodule that may bleed and ulcerate. Nodular melanomas may be heavily pigmented, or relatively amelanotic and erythematous, and may be confused with benign vascular lesions. A rim of pigmentation may, however, be seen under the dermatoscope. Lesions may develop de novo or from a pre-existing naevus or SSM.

Lentigo maligna melanoma

This arises from a prolonged pre-invasive phase termed lentigo maligna. It occurs as a very slowly expanding, pigmented, macular lesion, usually on photo-exposed head and neck sites of older patients; histology shows in situ changes only. This phase may last for several years before a nodule of invasive melanoma develops in a proportion of cases (lentigo maligna melanoma).

Acral lentiginous or palmoplantar melanoma

This accounts for only approximately 10% of melanomas in light-skinned races and is more common in dark-skinned people, in whom it is responsible for 50% of cases. This indicates that UVR exposure may not be implicated in acral melanoma risk.

Subungual melanoma

This form of melanoma is rare. It may present as a painless, proximally expanding streak of pigmentation arising from the nail matrix and progresses to nail dystrophy and involvement of the adjacent nail fold (Hutchinson sign).

Diagnosis and management

The diagnosis is made by excision biopsy of a suspicious lesion. The initial biopsy should include a 2–5 mm margin depending on level of suspicion, followed up where possible by wider excision if the diagnosis is confirmed. For stage 0 melanoma, a minimum of a 5 mm margin may be considered for therapeutic purposes. Occasionally, radiotherapy or imiquimod may be used for lentigo maligna, if surgery is not feasible. The Breslow thickness of the tumour (the maximal depth from epidermal

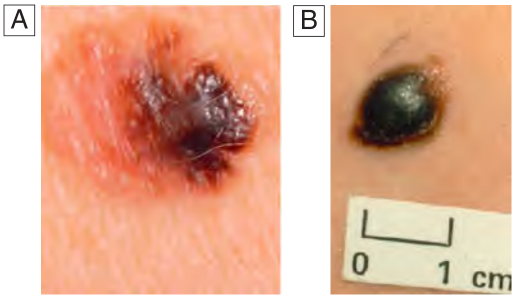

Fig. 26.16 Superficial spreading melanoma. **A** A superficial spreading malignant melanoma with a palpable area indicative of vertical growth phase (Breslow thickness 1.3 mm). **B** A nodular malignant melanoma arising de novo and with Breslow thickness of 3.5 mm.

granular cell layer to deepest tumour cells) is critical for management and prognosis. The presence of ulceration may lead to under-estimation of the Breslow thickness and may also adversely affect prognosis. The mitotic rate and the presence or absence of any evidence of lymphovascular or perineural involvement should also be ascertained. The clinical staging of melanoma extent is essential to establish whether disease is primary and localised, or if there is nodal or metastatic spread.

Wide excision of melanoma with a low risk of metastasis (stage 1 disease, Breslow thickness < 0.8 mm) with a 1 cm clear margin is accepted practice. The margin of excision for more advanced disease is debated, with at least a 2 cm margin advised for stage II melanoma and 2–3 cm for thicker tumours is generally advised as an attempt to reduce risk of local recurrence. There is no evidence that more radical surgery with 4–6 cm margins is beneficial. Most tumours can be excised without the need for more complex reconstruction. For tumours with a Breslow thickness of 0.8–1.0 mm or more, a sentinel lymph node biopsy may be considered and undertaken on a case-by-case basis as, in addition to provision of prognostic information, a positive sentinel node biopsy may facilitate access to adjuvant treatment with either targeted therapy and/or immune checkpoint inhibitors and entry to clinical trials of new treatments. Patients must be counselled about the sentinel node biopsy procedure, which is usually performed at the time of wider excision. It involves injection of radio-labelled blue dye at the site of the primary melanoma, allowing identification of the draining 'sentinel' node by radioscintigraphy; this sentinel node is then removed and examined in detail by histology, immunohistochemistry and/or PCR of melanocyte gene products to look for tumour deposits.

If the biopsy is positive, adjuvant therapy should be considered, as described below, and has largely replaced the need for complete local lymphadenectomy, which is a procedure that is associated with high morbidity in terms of lymphoedema and has no proven survival benefit. Nowadays it is only undertaken if there is a high risk of bulky locoregional recurrence.

Localised cutaneous or nodal recurrence may be treated surgically and cutaneous metastases or in-transit disease may be amenable to palliation with electrochemotherapy if there is no evidence of widespread metastatic disease. Systemic anti-cancer therapy, isolated limb perfusion, talimogene laherparepvec, imiquimod or radiotherapy may also be considered in this setting, if there is no evidence of bone, brain or internal organ metastasis.

There have been major advances in treatment options for advanced melanoma, such that patients are often now able to have extended survival, sometimes for many years. However, ultimately the overall prognosis for metastatic disease remains guarded, although those patients who respond to treatment may achieve long-term disease control. Genetic developments have facilitated the introduction of tumour-targeted treatments for advanced, unresectable and/or metastatic disease, such as the *B-Raf* and *c-Kit* kinase inhibitors for patients expressing these gene mutations, notably dabrafenib and vemurafenib, with demonstrable clinical responses. Combined BRAF and MEK targeted inhibition, with drugs such as trametinib, may also be used, with dabrafenib combined with trametinib as adjuvant treatment approach for BRAF V600 mutation-positive melanoma, with evidence showing improved disease-free survival compared to monotherapy. Immune checkpoint inhibition with ipilimumab, which causes T-cell activation by inhibiting CTLA-4, alone or in combination with the PD-1 pathway blockers nivolumab or pembrolizumab, provides clinically meaningful improvements in quality of life and survival to patients with advanced disease, with pembrolizumab as adjuvant treatment for resected stage III melanoma and nivolumab for adjuvant treatment of resected melanoma with lymph node involvement or metastatic disease. Standard chemotherapy may also be used in some cases of metastatic disease, although outcomes are poor. Other biologic and gene therapies and vaccines are also being investigated. It is important for patients with advanced melanoma to be managed through an MDT to optimise care, provide access to adjuvant therapy and facilitate inclusion in clinical trials.

All patients should be advised regarding ongoing photoprotection, with sensible behaviour in the sun, covering up, wearing hats and high-factor sunscreen use. However, evidence has shown that despite patients with melanoma being advised to photoprotect, many follow this advice only for the first year following diagnosis, thus emphasising the need for ongoing reinforcement of guidance regarding photoprotection. It is also advisable for patients to optimise oral vitamin D through diet and/or supplements.

Prognosis

Prognosis is influenced by several factors, including tumour characteristics and thickness (Breslow thickness) and the presence or absence of regional, nodal or metastatic disease. Patients with in situ melanoma do not have a risk of metastasis and those with an invasive primary tumour of less than 1 mm Breslow thickness have more than a 90% chance of 5-year disease-free survival, but this figure drops to approximately 50% for a tumour of greater than 3.5 mm thickness. Survival rates fall to less than 10% for those with advanced nodal or metastatic disease, but prolonged duration of survival with good quality of life is now possible with targeted therapies.

Benign skin lesions

In practice, it is often difficult to distinguish between skin cancer and a benign lesion on clinical grounds; if there is any doubt, biopsy and histology are required. Notably, benign melanocytic naevi and basal cell papilloma (seborrhoeic keratosis) can often be mistaken for melanoma, even by dermatologists. Keratoacanthoma, while benign, is also commonly considered to be an invasive SCC on clinical grounds.

Keratoacanthoma

This benign tumour has a striking clinical presentation of rapid growth over weeks to months and subsequent spontaneous resolution. It is thought to be associated with chronic sun exposure and most commonly occurs on the central face. The classical appearance is of an isolated dome-shaped nodule often of 5 cm or more in diameter, with a central keratin plug (Fig. 26.17). Clinically and histologically, the lesion often resembles SCC (see Fig. 26.13A). Most are treated surgically, either by curettage and cautery or by excision, to rule out SCC and to avoid the unsightly scar after spontaneous resolution.

Freckle

Histologically, a freckle (ephelis) consists of normal numbers of melanocytes, but with focal increases in melanin in keratinocytes. They are most

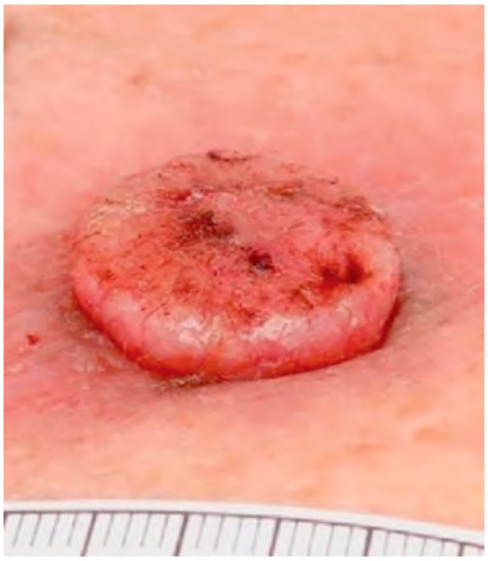

Fig. 26.17 Keratoacanthoma.

common on sun-exposed sites in light-skinned individuals, particularly children and those with red hair, and on the face. There is a familial tendency. Clinically, freckles are brown macules that darken following UVR exposure.

Lentigo

A lentigo (plural lentigines) consists of increased numbers of melanocytes along the basement membrane, but without formation of the nests that occur in melanocytic naevi. These lesions usually occur at sites of chronic sun exposure (see the background skin changes in Fig. 26.13A), become more common with age, and are often referred to as 'liver spots' or 'age spots'. They can vary in colour from light to very dark brown. Distinction from melanoma is essential and histology may be required.

Haemangiomas

Benign vascular tumours or hamartomas are common and include Campbell de Morgan spots (see Fig. 26.18), which present as pink/red papules on the upper half of the body. They can sometimes be difficult to distinguish from melanocytic lesions, particularly if they are thrombosed or occur on certain sites, such as the lip or genitalia. The dermatoscope is helpful for diagnosis (see Fig. 26.2).

Basal cell papilloma (seborrhoeic keratosis)

Basal cell papillomas (also known as seborrhoeic warts or keratoses) are common, benign epidermal tumours (Fig. 26.18). They may be flat, raised, pedunculated or warty-surfaced, and can appear to be 'stuck on'. They occur in both sexes, with increasing age and are most common on the face and trunk. The colour may vary from yellow to almost black and the surface may seem 'greasy', with pinpoint keratin plugs visible, particularly with a magnifying lens. If there is no doubt about the diagnosis, they can be left alone or treated by cryotherapy or curettage if they are cosmetically troublesome. If there is a suspicion of melanoma, excision or diagnostic biopsy should be undertaken.

Melanocytic naevi

Melanocytic naevi (moles) are localised benign clonal proliferations of melanocytes. It is thought that they may arise as the result of abnormalities in the normal migration of melanocytes during development. It is quite normal to have 20–50, although, interestingly, individuals with red hair have fewer. Genetic and environmental factors are implicated. Monozygotic twins have higher concordance in naevi numbers than dizygotic twins. Individuals who have had greater sun exposure have higher numbers of naevi. Most melanocytic naevi appear in childhood and early adult life, or during pregnancy or oestrogen therapy. The onset of a new mole is less common after the age of 25 years. Congenital melanocytic naevi occur at or shortly after birth.

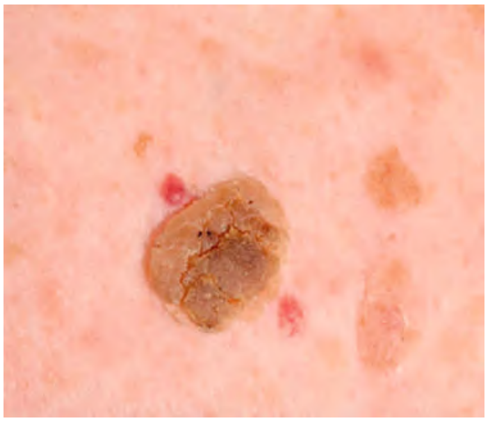

Fig. 26.18 A typical basal cell papilloma. Note the neighbouring basal cell papillomas and the coincidental benign angiomas (Campbell de Morgan spots).

Clinical features

Acquired melanocytic naevi are classified according to the microscopic location of the melanocyte nests (Fig. 26.19). Junctional naevi are usually macular, circular or oval, and mid- to dark brown. Compound and intradermal naevi are nodules because of the dermal component and may be hair-bearing. Intradermal naevi are usually less pigmented than compound naevi. Their surface may be smooth, cerebriform, hyperkeratotic or papillomatous.

Some individuals have large numbers of naevi, often at unusual sites, such as the scalp, palms or soles, and these may frequently appear 'atypical' in terms of variability in pigmentation, size and shape. Some may be very dark or pink and may show a depigmented or inflamed halo. If these naevi are removed, then 'dysplastic changes' are often seen. Such naevi are known to occur in some rare families with an inherited melanoma predisposition. However, the significance of such changes in non-familial cases is unclear and there is no consensus on management and follow-up.

Although approximately 50% of melanomas arise in pre-existing naevi, most naevi do not become malignant; although a changing naevus must be taken seriously, most will not be melanomas. Malignant change is most likely in large congenital melanocytic naevi (risk may correlate with size of lesion) and possibly in families where there is a history of large numbers of atypical naevi and/or a history of melanoma.

Diagnosis and management

Melanocytic naevi are normal and do not require excision, unless malignancy is suspected or they become repeatedly inflamed or traumatised. Advice on photoprotection is important for light-skinned individuals with multiple naevi.

Blue naevi

These are melanocytic naevi in which there is a proliferation of spindled melanocytes relatively deep within the dermis. Light scattering means that the pigment appears blue rather than brown. They may be difficult to distinguish from nodular melanoma and are therefore often excised.

Dermatofibroma

A dermatofibroma is a characteristically firm, often pigmented, raised lesion, typically found on the lower legs. Its aetiology is unclear, although a reactive process secondary to insect bites or trauma is one hypothesis. There is frequently a ring of pigment around the lesion and dimpling when the skin is pinched, reflecting epidermal tethering.

Acrochordon

Acrochordons, or skin tags, are benign pedunculated lesions; they are most common in skin flexures and usually have a very characteristic clinical appearance. However, they may sometimes be confused with

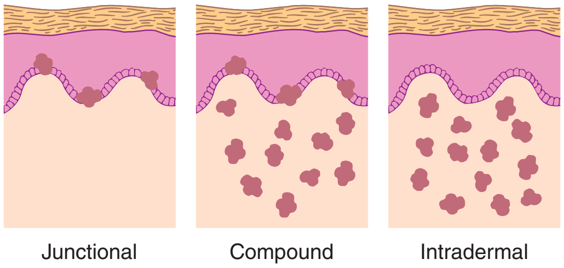

Fig. 26.19 Classification of melanocytic naevi. Classification is based on microscopic location of the nests of naevus cells.

melanocytic naevi. Treatment is not required unless there is diagnostic doubt or they are causing symptoms, such as irritation, or for cosmetic reasons. Cryotherapy or snip or shave excision may be appropriate in that situation.

Lipoma

Lipomas are benign tumours of adipocytes that are characteristically soft and lie more deeply in the skin than epidermal tumours; they are usually diagnosed easily on clinical grounds. A variant, angiolipoma, is typically painful. Treatment is not required unless there is diagnostic doubt or they are symptomatic or cosmetically troublesome, in which case a diagnostic biopsy or surgical excision may be required.

Common skin infections and infestations

Bacterial infections

Impetigo

Impetigo is a common and highly contagious superficial bacterial skin infection. There are two main presentations: bullous impetigo, caused by a staphylococcal epidermolytic toxin, and non-bullous impetigo (Fig. 26.20), which can be caused by either *Staphylococcus aureus* or streptococci, or both together. *Staphylococcus* spp. are the most common agents in temperate climates, whereas streptococcal impetigo is more often seen in hot, humid areas. All ages can be affected but non-bullous disease particularly affects young children, often in late summer. Outbreaks can arise in conditions of overcrowding and poor hygiene or in institutions. A widespread form can occur in neonates. Predisposing factors are minor skin abrasions and the existence of other skin conditions, such as infestations or eczema.

In non-bullous impetigo, a thin-walled vesicle develops; it rapidly ruptures and is rarely seen intact. Dried exudate, forming golden crusting, arises on an erythematous base. In bullous disease, the toxins cleave desmoglein-1, causing a superficial epidermal split and the occurrence of intact blisters with clear to cloudy fluid, which last for 2–3 days. The face, scalp and limbs are commonly affected but other sites can also be involved, particularly if there are predisposing factors such as eczema. Lesions may be single or multiple and coalesce. Constitutional symptoms are uncommon. A bacterial swab should be taken from blister fluid or an active lesion before treatment commences. Around one-third of the population is a nasal carrier of *Staphylococcus*, so swabs from the nostrils should also be obtained.

In mild, localised disease, topical treatment with mupirocin or fusidic acid is usually effective and limits the spread of infection. The use of topical antiseptics and soap and water to remove infected crusts is also helpful. Staphylococcal carriage should be treated, with mupirocin topically to the nostrils, if swabs are positive. In severe cases, an oral antibiotic, such as flucloxacillin or clarithromycin, is indicated. If nephritogenic streptococci are isolated then systemic antibiotics should be considered to reduce the risk of streptococcal glomerulonephritis. Underlying disease, such as infestations, must be treated and cross-infection minimised. Scarring does not occur but there may be temporary dyspigmentation.

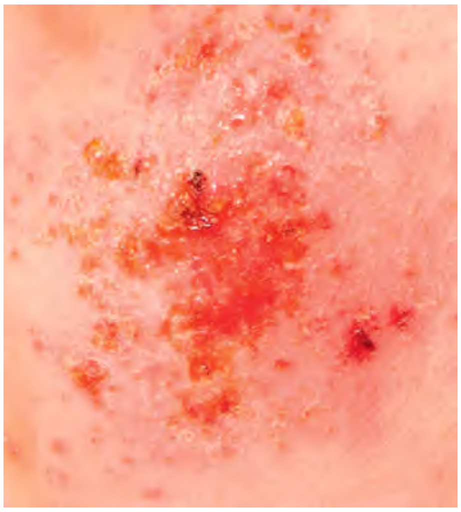

Fig. 26.20 **Non-bullous impetigo.**

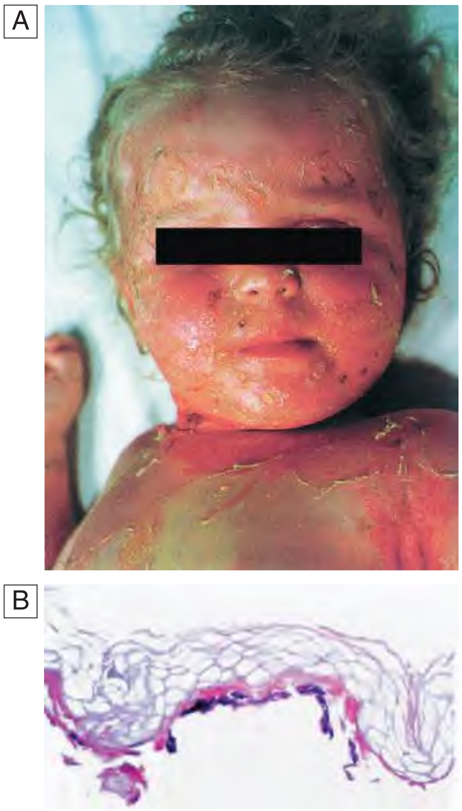

Fig. 26.21 **Staphylococcal scalded skin syndrome.** **A** Extensive erythema and superficial peeling of the skin. **B** The condition was rapidly diagnosed by examination of a frozen section of skin snip. *(A) From Savin JA, Dahl M, Hunter JAA. Clinical dermatology. 3rd ed. Oxford: Blackwell; 2002.*

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS) is a potentially serious exfoliating condition occurring predominantly in children, particularly neonates (Fig. 26.21). It is caused by systemic circulation of epidermolytic toxins from a *Staphylococcus aureus* infection. The same toxins are implicated in bullous impetigo, which is a localised form of SSSS. The focus of infection may be minor skin trauma, the umbilicus, urinary tract or nasopharynx. The child presents with fever, irritability and skin tenderness. Erythema usually begins in the groin and axillae, and around the mouth. Blisters and superficial erosions develop over 1–2 days and can rapidly involve large areas, with severe systemic upset. Bacterial swabs should be obtained from possible primary sites of infection. A skin snip should also be taken for urgent histology. This is a sample of the superficial peeling skin removed by ‘snipping with scissors’, without the need for local anaesthetic. It shows a split beneath the stratum corneum, and differentiates SSSS from toxic epidermal necrolysis, in which the whole epidermis is affected (see Fig. 26.41). Systemic antibiotics and intensive supportive measures should be commenced immediately. Bacterial swabs from nostrils, axillae and groins should be taken from family members to exclude staphylococcal carriage. Although the acute presentation of SSSS is often severe, rapid recovery and absence of scarring are usual, as the epidermal split is superficial.

Toxic shock syndrome

This condition is characterised by fever, desquamating rash, circulatory collapse and multi-organ involvement. It is caused by staphylococcal toxins, and early cases were thought to arise with tampon use. Intensive supportive care and systemic antibiotics are required.

Ecthyma

Ecthyma is caused by either staphylococci or streptococci, or both together, and is characterised by adherent crusts overlying ulceration. It occurs worldwide but is more common in the tropics. In Europe, it occurs more frequently in children. Predisposing factors include poor hygiene, malnutrition and underlying skin disease, such as scabies. It is commonly seen in drug abusers, and minor trauma can predispose to lesion development. Management approaches are similar to impetigo as ecthyma can be considered as a deeper version of impetigo. Crust removal, antiseptics and systemic antibiotics may be required.

Folliculitis, furuncles and carbuncles

Hair follicle inflammation can be superficial, involving just the ostium of the follicle (folliculitis), or deep (furuncles and carbuncles).

Superficial folliculitis

The primary lesions are follicular pustules and erythema. Superficial folliculitis is often infective, caused by *Staphylococcus aureus*, but can also be sterile and caused by physical (for example, traumatic epilation) or chemical (for example, mineral oil) injury. Staphylococcal folliculitis is most common in children and often occurs on the scalp or limbs. Pustules usually resolve without scarring in 7–10 days but can become chronic. In older children and adults, they may progress to a deeper form of folliculitis. The condition is often self-limiting and may respond to irritant removal and antiseptics. More severe cases may require topical or systemic antibiotics and treatment of *Staphylococcus aureus* carrier sites.

Deep folliculitis (furuncles and carbuncles)

A furuncle (boil) is an acute *Staphylococcus aureus* infection of the hair follicle, usually with necrosis. It is most common in young adults and males. It is usually sporadic, but epidemics occasionally occur. Malnutrition, diabetes and HIV predispose, although most cases arise in otherwise healthy people. All body sites can be involved but neck, buttocks and anogenital areas are commonly affected areas. Infection is often associated with chronic *Staphylococcus aureus* carriage in the nostrils and perineum, and may be due to resistant strains, such as methicillin-resistant organisms (MRSA). Friction caused by tight clothing may be contributory. Initially, an inflammatory follicular nodule develops and becomes pustular, fluctuant and tender. Crops of lesions sometimes occur. There may be fever and mild constitutional upset. Lesions rupture over days to weeks, discharge pus, become necrotic and leave a scar.

If a deep *Staphylococcus aureus* infection of a group of contiguous hair follicles occurs, this is termed a carbuncle and is associated with intense deep inflammation (Fig. 26.22). This usually occurs in middle-aged men, often with predisposing conditions such as diabetes or immunosuppression. A carbuncle is an exquisitely tender nodule, usually on the neck, shoulders or hips, associated with severe constitutional symptoms. Discharge, necrosis and scarring are usual. Bacterial swabs must be taken, and treatment is with anti-staphylococcal antibiotics, e.g. flucloxacillin, and sometimes incision and drainage.

Other staphylococcal toxins may also be pathogenic. For example, Panton–Valentine leucocidin (PVL)-producing *Staphylococcus aureus* can cause recurrent abscesses (definition: localised collections of pus in cavities) and may be difficult to eradicate.

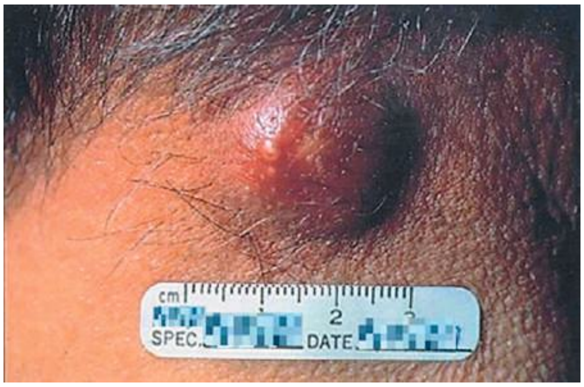

Fig. 26.22 **Staphylococcal carbuncle.**

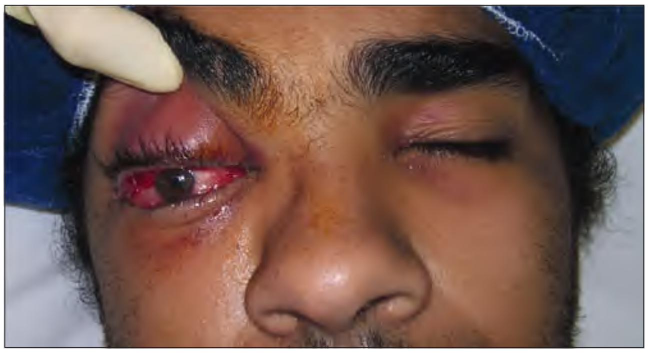

Fig. 26.23 **Severe right orbital cellulitis.** There is proptosis, chemosis, reduced ocular motility and reduced vision. *From Yanoff M, Duker JS. Ophthalmology. 5th ed. Elsevier; 2019.*

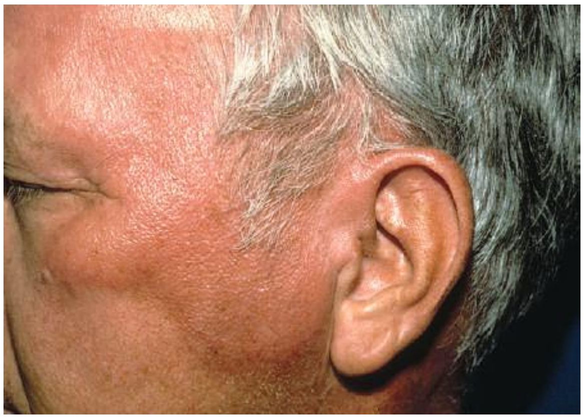

Fig. 26.24 **Erysipelas.** *From Schwarzenberger K, Werchniak A, Ko C. General dermatology. Elsevier; 2009.*

Cellulitis and erysipelas

Cellulitis is inflammation of subcutaneous tissue, due to bacterial infection (Fig. 26.23). In contrast, erysipelas is bacterial infection of the dermis and upper subcutaneous tissue (Fig. 26.24), although in practice it may be difficult to distinguish between them. These conditions are usually caused by group A streptococci but culture of swabs from affected sites is often negative. There is frequently a source of organism entry, such as an ear infection, varicose eczema/ulcer or tinea pedis, and swabs should also be taken from these sites. Diabetes and immunosuppression are predisposing factors. The patient usually has malaise, fever and leucocytosis, and streptococcal serology will often be positive. The face (erysipelas) and legs (cellulitis) are most often affected, and the site is hot, painful, erythematous and oedematous. Blistering often occurs and may be haemorrhagic. Regional lymphadenopathy is common. Erysipelas typically has a well-defined edge due to its more superficial level of involvement, whereas cellulitis is typically ill-defined. Treatment is usually with intravenous flucloxacillin, with clarithromycin, clindamycin and vancomycin as alternatives for penicillin-allergic patients. Milder cases may be treated with oral antibiotics. If cases are untreated, sequelae include lymphoedema, cavernous sinus thrombosis, sepsis and glomerulonephritis.

Mycobacterial infections

Mycobacterium leprae infection may involve the skin and its manifestations will be influenced by host immunity, patients with high levels of immunity presenting with paucibacillary tuberculoid leprosy and those with low immune resistance developing multibacillary lepromatous leprosy. Hypopigmented or erythematous patches, with associated altered or lost sensation, or skin thickening, nodules and infiltration should raise suspicion of a diagnosis of leprosy. The skin may also be an extrapulmonary site of involvement in tuberculosis, usually due to infection with *Mycobacterium tuberculosis*. Skin manifestations depend on the route of infection, previous sensitisation and host immunity. There may be a variety of cutaneous features, including the red–brown scarring inflammatory plaques seen in lupus vulgaris due to direct skin inoculation; scrofuloderma, which describes the skin changes overlying lymph nodes or joints infected with tuberculosis; and the reactive nodular and ulcerated changes seen in patients with high levels of immune response, notably the tuberculids and erythema induratum (Bazin disease). On diascopy, an 'apple jelly' appearance is typically seen, indicating the granulomatous nature of skin involvement. Granulomas evident on skin biopsy should certainly raise suspicion of a diagnosis of mycobacterial infection. Culture of organisms may be difficult, but PCR can assist with diagnosis. Patients should be thoroughly investigated for signs of tuberculosis at pulmonary or other extrapulmonary sites. Reactivation of latent tuberculosis is a particular concern for patients receiving treatment with immunosuppressants and biologic agents, particularly TNF-α antagonists for conditions such as psoriasis. Vigilance is required in screening and workup of such patients prior to consideration of these therapeutic agents. Management of tuberculosis is discussed in Chapter 17.

Other mycobacterial skin infections may occur, such as *Mycobacterium marinum*, typically seen in those who clean tropical fish tanks. Sporotrichoid spread of granulomatous nodules from the site of inoculation along lymphatics is typical; granulomatous changes are seen on histology and resolution usually occurs with a prolonged course of antibiotics such as doxycycline or minocycline. Resolution may also take place spontaneously or after destructive therapies, such as cryotherapy.

Leishmaniasis

This protozoan infection may be restricted to the skin or there may be systemic features depending on the species, which occur in different geographical areas. The clinical features and management of this condition are discussed in Chapter 14.

Necrotising soft tissue infections and anthrax

These conditions are discussed in more detail in Chapter 14.

Erythrasma

Erythrasma is a mild, chronic, localised, superficial skin infection caused by *Corynebacterium minutissimum*, which is part of the normal skin flora. Warmth and humidity predispose to this infection, which usually occurs in flexures and toe clefts. It is asymptomatic or mildly itchy and lesions are well defined, red–brown and scaly. *C. minutissimum* has characteristic coral-pink fluorescence under Wood's light. Microscopy and culture of skin scrapings can confirm the diagnosis but are not usually needed if Wood's light examination is positive. A topical azole (clotrimazole or miconazole) or fusidic acid is usually effective. Oral erythromycin can be used for extensive or resistant disease. Antiseptics can be used to prevent disease recurrence.

Pitted keratolysis

This is another superficial skin infection caused by *Corynebacterium* and *Streptomyces* spp., and possibly other organisms, producing characteristic circular erosions ('pits') on the soles. It is usually asymptomatic. The bacterium can be identified in skin scrapings and typically occurs in association with hyperhidrosis, which must be treated to prevent recurrence. Treatment is as for erythrasma.

Other bacterial skin infections

Syphilis and the non-venereal treponematoses are discussed in Chapter 15. There has been a marked increase in incidence of syphilis. Skin signs may be subtle; for example, secondary syphilis may be misdiagnosed as pityriasis rosea. Lesions on palms, soles and mucosae should raise suspicion. Microscopic identification of the spirochaete may be possible, and syphilitic serology should be undertaken using enzyme immunoassay or PCR-based techniques, depending on availability. Lyme disease can also cause a skin rash; the clinical features and management are described in Chapter 14.

Viral infections

Herpesvirus infections

The cutaneous manifestations of the human herpesviruses are described in more detail in Chapter 14. Topical antivirals may suffice for prophylaxis or treatment of mild viral disease, such as herpes simplex cold sore virus infection. Systemic antivirals are indicated for significant viral skin disease. For example, systemic aciclovir should be prescribed for eczema herpeticum (see Fig. 14.29C).

Papillomaviruses and viral warts

Viral warts are extremely common and are caused by the DNA human papillomavirus (HPV). There are over 90 subtypes, based on DNA sequence analysis, causing different clinical presentations. Transmission is by direct virus contact, in living or shed skin, and is encouraged by trauma and moisture, such as in swimming pools. Genital warts are spread by sexual activity and show a clear relationship with cervical and intra-epithelial cancers of the genital area. HPV-16 and -18 appear to inactivate tumour suppressor gene pathways and lead to squamous cell carcinoma of the cervix or intra-epithelial carcinoma of the genital skin. Vaccinations are available against HPV-16 and -18 and are recommended for females and males aged 12–13 years, before they become sexually active, with the objective of offering protective effects against cervical, genital, anal and some head and neck malignancies. The relationship between skin HPV and skin cancer is unclear. Individuals who are systemically immunosuppressed – after organ transplantation, for example – have greatly increased risks of both skin cancer and HPV infection but a causal link is not certain.

Clinical features

Common warts are initially smooth, skin-coloured papules, which become hyperkeratotic and 'warty'. They are most common on the hands (Fig. 26.25) but can occur on the face, genitalia and limbs, and are often multiple. Plantar warts (verrucae) have a slightly protruding rough surface and horny rim and are often painful on walking. Paring reveals capillary loops that distinguish plantar warts from corns. Other varieties of wart include:

- *mosaic warts*: mosaic-like sheets of warts
- *plane warts*: smooth, flat-topped papules, usually on the face and backs of hands, which may be pigmented and therefore misdiagnosed

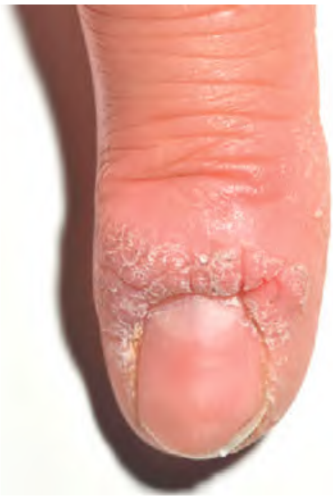

Fig. 26.25 Viral wart on the finger. The capillary loops are evident within the warty hyperkeratosis. Periungual sites are common and more difficult to treat.

- *facial warts*: often filiform
- *genital warts*: may be papillomatous and exuberant

Management

Most viral warts resolve spontaneously, although this may take years, and active treatment is therefore often sought. However, asymptomatic warts generally should not be treated. Viral warts are particularly problematic and more recalcitrant to treatment in immunosuppressed patients following organ transplantation.

Treatments are destructive. Salicylic acid or salicylic/lactic acid combinations and regular wart paring for several months are the most consistently effective treatments. For certain types of warts, such as filiform facial warts, cryotherapy is generally the treatment of choice, but for common hand and foot warts salicylic acid wart paint should be used first. Cryotherapy is usually the next step and is repeated 2- to 4-weekly. However, caution is required, particularly on the hands, as over-vigorous cryotherapy can lead to scarring, nail dystrophy and even tendon rupture. Periungual and subungual warts can be problematic and cutting the nails and subsequent electrodesiccation may help. Several other therapies have been used for recalcitrant warts, including topical formaldehyde, glutaraldehyde, podophyllotoxin, trichloroacetic acid, cantharidin, topical or systemic retinoids, intralesional bleomycin or interferon injections, and contact sensitisation with, for example, diphencyprone. Imiquimod and PDT may also be beneficial, particularly for multiple warts in immunosuppressed patients, and laser therapy can have a role in some cases.

Molluscum contagiosum

Molluscum contagiosum is caused by a DNA poxvirus skin infection. It is most common in children over the age of 1 year, particularly those with atopic dermatitis. It also occurs frequently in immunosuppressed patients, including those with HIV. Lesions are dome-shaped, 'umbilicated', skin-coloured papules with central punctum (Fig. 26.26). They are often multiple and found at sites of apposition, such as the side of the chest and the inner arm. Spontaneous resolution occurs but can take months. Prior to resolution, they often become inflamed and may leave small, atrophic scars. Destructive therapies may be painful and risk scarring, and the decision not to treat is often sensible. Gentle squeezing with forceps after bathing can hasten resolution. If active treatment is needed, topical salicylic acid, potassium hydroxide, podophyllin, cantharidin, trichloroacetic acid, imiquimod, cryotherapy, diathermy, curettage or laser treatment are therapeutic approaches that can be considered.

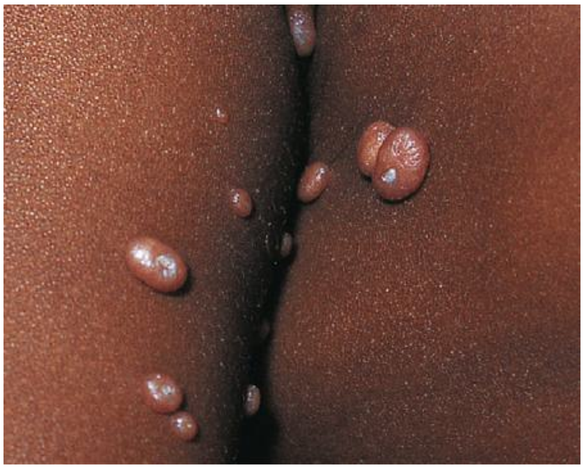

Fig. 26.26 Molluscum contagiosum. Some of the pearly lesions show characteristic umbilication. *From Lissauer T, Carroll W. Illustrated textbook of paediatrics. 6th ed. Elsevier; 2022.*

Orf

Orf is a parapoxvirus skin infection and is an occupational risk for those who work with sheep and goats. Inoculation of virus, usually into finger skin, causes significant inflammation and necrosis, which typically resolves within 2–6 weeks. No specific treatment is required, unless there is secondary infection. Erythema multiforme can be provoked by orf.

Other viral exanthems

Skin rash can be a feature of various other virus infections, and these are discussed in more detail in Chapter 14.

Fungal infections

Fungal skin infections can be superficial (dermatophytes and yeasts) or, less commonly, deep (chromomycosis or sporotrichosis); the latter are seen more often in tropical climates or in the immunocompromised. Dermatophyte infections (ringworm) are extremely common and usually caused by fungi of the *Microsporum*, *Trichophyton* and *Epidermophyton* species. The fungi can originate from soil (geophilic), animals (zoophilic) or be confined to human skin (anthropophilic). Dermatophyte infections usually present with skin (tinea corporis), scalp (tinea capitis), groin (tinea cruris), foot (tinea pedis) and/or nail (onychomycosis) involvement (Fig. 26.27).

Diagnosis

Skin scrapings, plucked hair or nail clippings must be taken from areas of disease activity – typically, the advancing lesion edge for skin involvement, the crumbling dystrophic nail and subungual hyperkeratosis for nail involvement, and plucked hair from scalp or other affected hair-bearing sites – to confirm the diagnosis by microscopy and culture.

Management

The azoles (ketoconazole, miconazole), triazoles (itraconazole, fluconazole) and triallylamines (terbinafine) are used most widely in fungal skin disease. Topical antifungals such as terbinafine or miconazole may suffice, although systemic treatment (terbinafine, itraconazole or griseofulvin) may be required for stubborn or extensive disease and scalp or nail involvement. Indeed, prolonged courses of systemic treatment may be needed for nail involvement. The fungistatic agent griseofulvin, given orally, is usually used for fungal infection of scalp or nails in children in the UK, as terbinafine is not licensed for use in children for this indication; outside the UK, and in adults, terbinafine is usually the treatment of choice as it has broader range of activity and shorter treatment duration. Itraconazole is also an effective alternative. In addition to systemic antifungals, short courses of systemic

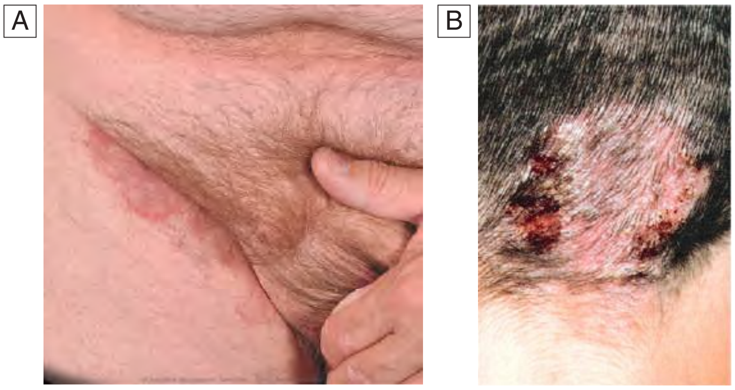

Fig. 26.27 Dermatophyte infections. **A** *Trichophyton rubrum* infection of the groin (tinea cruris). **B** *Microsporum canis* infection of the scalp (tinea capitis).

or topical glucocorticoid are often used in kerion with the aim of reducing inflammation and possible hair loss. However, glucocorticoid use is controversial, with no good evidence of benefit.

Tinea corporis

Tinea corporis should feature in the differential diagnosis of a red, scaly rash. Typically, lesions are erythematous, annular and scaly, with a well-defined edge and central clearing. There may also be pustules at the active edge. Lesions are usually asymmetrical and may be single or multiple. The degree of inflammation is dependent on the organism involved and the host immune response. *Microsporum canis* (from dogs) and *Trichophyton verrucosum* (from cats) are common culprits. Ill-advised use of topical glucocorticoids can modify the clinical presentation and increase disease extension (tinea incognito).

Tinea cruris

This is extremely common worldwide and is usually caused by *T. rubrum*. Itchy, erythematous plaques develop in the groin and extend on to the thighs, with a raised active edge (see Fig. 26.27A).

Tinea pedis

Tinea pedis or ‘athlete’s foot’ is the most common fungal infection in the UK and USA, and is usually caused by anthropophilic fungi, such as *T. rubrum*, *T. interdigitale* and *Epidermophyton floccosum*. It typically presents as an itchy rash between the toes, with peeling, fissuring and maceration. Involvement of one sole or palm (tinea manuum) with fine scaling is characteristic of *T. rubrum* infection. Vesiculation or blistering is more often seen with *T. mentagrophytes*.

Tinea capitis

This is a dermatophyte infection of scalp hair shafts and is most common in children. It typically presents as an area of scalp inflammation and scaling, often with pustules and partial hair loss (see Fig. 26.27B). Infection may be within the shaft (endothrix, most commonly caused by *T. tonsurans*), causing patchy hair loss with broken hairs at the surface (‘black dot’), little inflammation and no fluorescence with Wood’s light. Infection outside the hair shaft (ectothrix, most commonly caused by *M. audouinii* (anthropophilic)) shows minimal inflammation; *M. canis* (from dogs and cats) infections are more inflammatory and can be identified by green fluorescence with Wood’s light. Kerion is a boggy, inflammatory area of tinea capitis, usually caused by zoophilic fungi such as cattle ringworm (*T. verrucosum*).

Onychomycosis

This is a fungal infection of the nail plate, and the species involved are generally those that cause tinea capitis or tinea pedis. Onychomycosis usually presents with yellow/brown nail discoloration, crumbling, thickening and subungual hyperkeratosis. Usually, some nails are spared, there is asymmetry, and toenails are more commonly involved.

Candidiasis

This is a superficial skin or mucosal infection caused by a yeast-like fungus, *Candida albicans*. Infections are usually not serious, unless the patient is immunocompromised, in which case deeper tissues can be involved. The organism has a predilection for warm, moist environments and typical presentations are napkin candidiasis in babies, genital and perineal candidiasis, intertrigo and oral candidiasis. The diagnosis can be confirmed by microscopy and culture of skin swabs, and treatment is with topical or systemic antifungals, such as azoles.

Pityriasis versicolor

Pityriasis versicolor is a persistent, superficial skin condition caused by various species of the commensal yeast *Malassezia*, most commonly *Malassezia globosa*, but sometimes *M. sympodialis* or *M. furfur*. This condition occurs in men and women and in different races. It is more common in warm, humid climates, and is usually more severe and persistent in the immunocompromised. It is characterised by scaly, oval macules on the upper trunk, usually hypopigmented but occasionally hyperpigmented. Hypopigmentation is more obvious after sun exposure and tanning. The diagnosis can be confirmed by microscopy of skin scrapings, showing ‘spaghetti and meatballs’ hyphae. Treatment with selenium sulphide or ketoconazole shampoos and topical or systemic azole antifungal agents is usually effective, although recurrence is common because these yeasts are skin commensals, and maintenance topical therapy may be required. Altered pigmentation can persist for months after treatment.

Infestations

Scabies

Scabies is a common condition, caused by the mite *Sarcoptes scabiei*. It spreads in households and environments where there is intimate personal contact. The diagnosis is made by identifying the scabietic burrow (definition: a linear or curvilinear papule, caused by a burrowing scabies mite – Fig. 26.28) and visualising the mite (by extracting with a needle or using a dermatoscope). In small children, the palms and soles can be involved, with pustules. Pruritus is prominent. The clinical features include secondary eczematisation elsewhere on the body; the face and scalp are rarely affected, except in infants. Involvement of the genitals in males and of the nipples commonly occurs. Even after successful treatment, itch can continue, and occasionally nodular lesions persist.

Topical treatment of the affected individual and all asymptomatic family members/physical contacts is required to ensure eradication. Two applications 1 week apart of an aqueous solution of permethrin or malathion to the whole body, excluding the head, are usually successful,

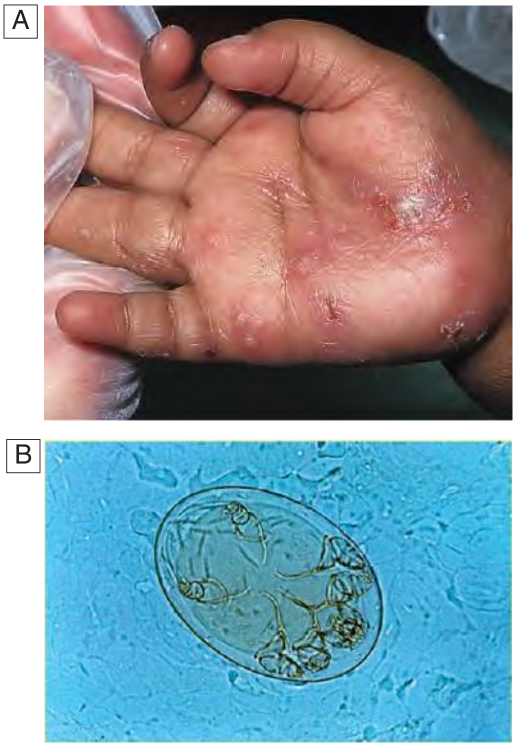

Fig. 26.28 Scabies. A Scabies in a young child affecting the palm. B A mite still in its egg, seen on light microscopy of scrapings over a burrow. Note that the mite has only six legs, unlike adult mites, which have eight. *(A) From Lissauer T, Carroll W. Illustrated textbook of paediatrics. 5th ed. Elsevier; 2018.*

although resistant disease has been increasingly observed. If there is poor adherence, immunosuppression or heavy infestation (crusted 'Norwegian' scabies), systemic treatment with a single oral dose of ivermectin is sometimes appropriate. Given emerging resistance, two doses of ivermectin one week apart is now recommended for scabies refractory to topical therapy.

Head lice

Infestation with the head louse, *Pediculus humanus capitis*, is common. It is highly contagious and spread by direct head-to-head contact. Scalp itch leads to scratching, secondary infection and cervical lymphadenopathy. The diagnosis is confirmed by identifying the living louse or nymph on the scalp or on a black sheet of paper after careful fine-toothed combing of wet hair following conditioner application. The empty egg cases ('nits') are easily seen on the hair shaft and are hard to dislodge.

Treatment is recommended for the affected individual and any infected household/school contacts. Eradication in school populations is difficult because of poor adherence and treatment resistance. Topical treatment with dimeticone, permethrin, carbaryl or, less often, malathion in lotion or aqueous formulations may be effective and should be applied twice at an interval of 7–10 days. Rotational treatments within a community may avoid resistance. 'Wet-combing' (physical removal of live lice by regular combing of conditioned wet hair – 'bug busting') can suffice but may be less effective than pharmacological treatments. Vaseline should be applied to eyelashes/brows twice daily for at least a fortnight. High temperature washing of clothing and bedding is required. Treatment resistance and recurrence can be problematic.

Body lice

These are like head lice but live on clothing, particularly in seams, and feed on the skin. Poor hygiene and overcrowded conditions predispose. Itch, excoriation (definition: a linear ulcer or erosion resulting from scratching) and secondary infection occur. Drycleaning and high temperature washing or insecticide treatment of clothes are required. Treatment options are as for head lice. For heavy infestation, oral ivermectin may be indicated.

26.16 Acne in adolescence

Epidemiology: acne vulgaris is most common between the ages of 12 and 20. It often begins around 10–13 years of age, lasts 5–10 years and usually resolves by age 20–25.

Emotional effects: at all ages acne can have negative effects on self-esteem, but it is especially important to assess how it affects an adolescent. Depression and suicidal ideation may occur. The consequences (whether acne is objectively severe or not) can be devastating, leading to embarrassment, school avoidance, and life-long effects on ability to form friendships, attract partners, and acquire and keep employment.

Treatment: effective treatments aim to improve the condition, prevent worsening (including later scarring) and restore emotional well-being and self-esteem.

Pubic (crab) lice

Usually, these are sexually acquired and very itchy. Management is as for head and body lice and whole-body treatment should be undertaken. Pubic hair may need to be shaved. Sexual and other close contacts should also be treated, and patients should be screened for sexually transmitted diseases.

Acne and rosacea

Acne vulgaris

Acne is chronic inflammation of the pilosebaceous units. It is extremely common, generally starts during puberty and has been estimated to affect over 90% of adolescents. It is usually most severe in later adolescence but can persist into the thirties and forties, particularly in females (Box 26.16).

Pathogenesis

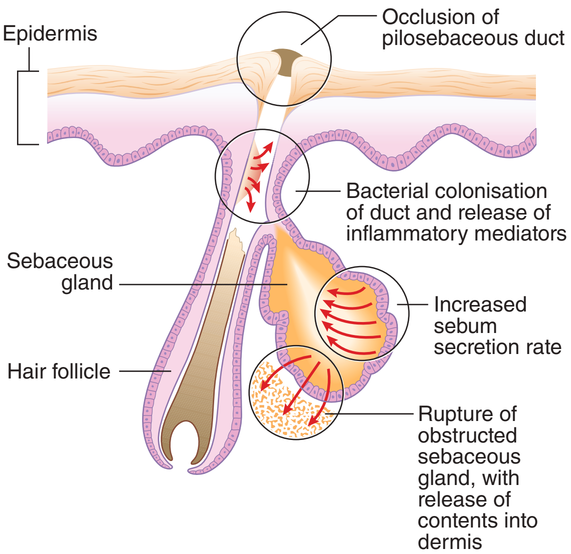
The key components are increased sebum production; colonisation of pilosebaceous ducts by *Cutibacterium acnes*, which in turn causes inflammation; and hypercornification and occlusion of pilosebaceous ducts (Fig. 26.29). Severity of acne is associated with sebum excretion rate, which increases at puberty. Both androgens and progestogens increase sebum excretion and oestrogens reduce it, but most patients with acne have normal hormone profiles. There may be a positive family history and there is high concordance in monozygotic twins, indicating that genetic factors are important, but the candidate genes are poorly defined.

Clinical features

Acne usually affects the face and often the trunk. Greasiness of the skin may be obvious (seborrhoea). The hallmark is the comedone (definition: open comedones (blackheads) are dilated keratin-filled follicles, which appear as black papules due to the keratin debris; closed comedones (whiteheads) usually have no visible follicular opening and are caused by accumulation of sebum and keratin deeper in the pilosebaceous ducts – see Fig. 26.29). Inflammatory papules, nodules and cysts occur and may arise from comedones (Fig. 26.30). Scarring may follow deep-seated or superficial acne and may be keloidal.

There are also distinct clinical variants:

- *Acne conglobata*: characterised by comedones, nodules, abscesses, sinuses (definition: cavities or channels that permit the escape of pus or fluid) and cysts, usually with marked scarring. It is rare, usually affecting adult males, and most commonly occurs on trunk and upper limbs. It may be associated with *hidradenitis suppurativa (acne inversa)* (an occlusive follicular



Epidermis
Occlusion of pilosebaceous duct
Bacterial colonisation of duct and release of inflammatory mediators
Sebaceous gland
Increased sebum secretion rate
Hair follicle
Rupture of obstructed sebaceous gland, with release of contents into dermis

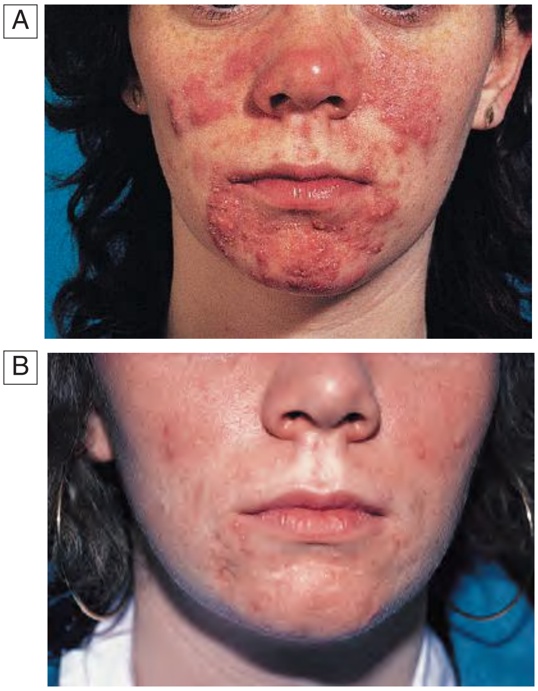

Fig. 26.30 **Cystic acne in an adolescent girl.** **A** Before treatment. **B** After prolonged systemic antibiotic treatment.

chronic inflammatory condition affecting apocrine glands; this predominantly affects axillae, groins, perineal and perianal sites and follows a relapsing and remitting course and often requires complex medical and surgical management approaches), scalp folliculitis and pilonidal sinus.

- *Acne fulminans*: a rare but severe presentation of acne, associated with fever, arthralgias and systemic inflammation, with raised neutrophil count and plasma viscosity. It is usually found on the trunk in adolescent males. Costochondritis can occur.
- *Acne excoriée*: self-inflicted excoriations due to compulsive picking of pre-existing or imagined acne lesions. It usually affects adolescent girls, and underlying psychological problems are common.
- *Secondary acne*: comedonal acne can be caused by greasy cosmetics or occupational exposure to oils, tars or chlorinated aromatic hydrocarbons. Predominantly pustular acne can occur in patients using systemic or topical glucocorticoids, oral contraceptives, anticonvulsants, lithium or antineoplastic drugs, such as the epidermal growth factor receptor (EGFR) inhibitors. Most patients with acne do not have an underlying endocrine disorder but acne is a common feature of polycystic ovary syndrome which should be suspected if acne is moderate to severe and associated with hirsutism and menstrual irregularities. Virilisation should also raise suspicion of an androgen-secreting tumour.

Investigations

Investigations are not required in typical acne vulgaris. Secondary causes and suspected underlying endocrine disease or virilisation should be investigated.

Management

Mild to moderate disease

Mild disease is usually managed with topical therapy. If comedones predominate, then topical benzoyl peroxide or retinoids should be used. Benzoyl peroxide has both anti-comedogenic and antiseptic effects. It is an irritant, which may contribute to the therapeutic response, but this can be minimised by adjusting treatment regimens. Azelaic acid may also be used for mild acne and has both antimicrobial and anti-comedogenic action. Topical retinoids, in particular *all-trans* retinoic acid and adapalene, are widely employed for mild to moderate comedonal acne vulgaris. Treatment should be initially applied at low concentrations for short duration and increased as tolerated. Patients with mild inflammatory acne should respond to topical antibiotics, such as erythromycin or clindamycin, which can be used in combination with other treatments.

For moderate inflammatory acne, a systemic tetracycline should be used at adequate dose for 3–6 months in the first instance (Fig. 26.30B). Oxytetracycline must be taken on an empty stomach, in a dose of up to 1.5 g a day. It has a good safety profile, even with long-term use, but adherence may be a challenge. Lymecycline is an alternative and is taken once daily, with or without food, thereby improving adherence. Doxycycline is another option but commonly causes photosensitivity. Minocycline is no longer used as it can cause hyperpigmentation, autoimmune hepatitis and drug-induced lupus. If the patient fails to respond, then alternatives include erythromycin or trimethoprim.

In women with acne, oestrogen-containing oral contraceptives can be a useful adjunct, as they are associated with a small reduction in sebum production. Combined oestrogen and anti-androgen (such as cyproterone acetate) contraceptives may provide additional efficacy, particularly in women with acne and hirsutism, as seen in polycystic ovary syndrome. Spironolactone should also be considered in this setting for women with acne.

Patients should be referred for consideration of isotretinoin (13-*cis*-retinoic acid) if there is a failure to respond adequately to 6 months of therapy with these combined systemic and topical approaches.

Moderate to severe disease

Isotretinoin (13-*cis*-retinoic acid) has revolutionised the treatment of moderate to severe acne that has not responded adequately to other therapies. It has multifactorial mechanisms of action, with reduction in sebum excretion by over 90%, follicular hypercornification, *C. acnes* colonisation and inflammation. Oral isotretinoin is usually used at a dose of 0.5–1 mg/kg over 4 months. Sebum excretion typically returns to baseline within a year after treatment cessation, although clinical benefit is usually of longer duration. Many patients will not require further treatment, although a repeat course of isotretinoin may sometimes be needed. A low-dose continuous or intermittent-dose regimen may occasionally be considered for a longer duration in patients who relapse after a higher-dose regimen and may also be beneficial for older females with persistent acne. Combination with systemic glucocorticoid may be required in the short term for severe acne, to minimise the risk of disease flare early in the isotretinoin course. Thorough screening and close monitoring are required, given the side-effect profile of isotretinoin, particularly with respect to teratogenicity and possible mood disturbance. Pregnancy must be avoided during treatment and for a minimum of 2 months after drug cessation, and a strict pregnancy prevention programme and regular pregnancy testing are required. Sexual dysfunction has also been proposed as a potential adverse effect, although no causal link to isotretinoin has been established. Depression and suicide have also been reported in association with isotretinoin, although again a causal role has not been established. However, pre-drug screening for depressive symptoms should be undertaken and mood monitored during therapy, along with enquiry regarding potential sexual dysfunction. A recent MHRA report, undertaken due to concerns about potential psychiatric and sexual dysfunction risks, has led to more rigorous guidance on prescribing and monitoring isotretinoin, particularly in under-18s where two clinicians must approve its prescribing, which may prove challenging to implement, raising some concern about possible under-use of this valuable therapy.

Other treatments and physical measures

Intralesional injections of triamcinolone acetonide may be required for inflamed acne nodules or cysts, which can also be incised and drained, or excised under local anaesthetic. Scarring may be prevented by adequate treatment of active acne. Keloid scars may respond to intralesional glucocorticoid and/or silicone dressings. Carbon dioxide laser, microdermabrasion, chemical peeling or localised excision can also be considered for scarring. UVB phototherapy or PDT can occasionally be used in patients with inflammatory acne who are unable to use conventional therapy, such as isotretinoin. There is no convincing evidence to support a causal association between diet and acne. The psychological impact of acne must not be under-estimated and should be considered in management decisions (see Box 26.16).

Rosacea

This chronic inflammatory condition affects the central face and consists of flushing, erythema, papules, pustules and telangiectasiae. The cause is unknown. Rosacea is distinct from acne vulgaris; sebum excretion is normal and comedones are absent. The relative contribution of *Demodex* mite and cutaneous vasomotor instability to the pathogenesis of rosacea remains poorly defined.

Clinical features

Rosacea most commonly affects light-skinned, middle-aged females and can be exacerbated by heat, sunlight and alcohol. The convexities of nose, forehead, cheeks and chin are typically involved (Fig. 26.31). The condition is heterogeneous and intermittent flushing, followed by fixed erythema and telangiectasiae, predominates in some; in others, papules and pustules are prominent. Sebaceous gland hyperplasia and soft tissue overgrowth of the nose (rhinophyma) can occur, particularly in males (see Fig. 26.31). Conjunctivitis and blepharitis may also occur. Facial lymphoedema can be an added complication.

Investigations

Usually, no investigations are required, and the diagnosis is obvious clinically. However, rosacea must be distinguished from acne vulgaris, systemic lupus erythematosus, photosensitivity disorders and seborrhoeic dermatitis (the latter may coexist with rosacea).

Management

Mild disease may respond to topical antimicrobials, such as metronidazole or azelaic acid. Topical ivermectin may be beneficial in some cases, supporting a contributory role of *Demodex* in rosacea pathogenesis. Tetracycline or erythromycin for 3–6 months is usually effective in inflammatory pustular disease resistant to topical therapy. Relapse may require intermittent or chronic antibiotic use. Erythema and telangiectasiae do not usually respond well to antibiotics but vascular laser therapy may be effective. Topical vasoconstrictors, such as the α_2-adrenoceptor agonist brimonidine, may be of benefit in some cases where erythema and telangiectasiae predominate. Systemic isotretinoin may be helpful in severe resistant disease and rhinophyma may require laser therapy or surgery.

26.17 Classification of eczema

Endogenous

- Atopic, seborrhoeic

Exogenous

- Irritant, allergic, photo-allergic, chronic actinic dermatitis

Characteristic patterns and morphology

- Asteatotic, discoid, gravitational, lichen simplex, pompholyx

Eczemas

The term 'eczema' derives from the Greek word 'to boil' and is synonymous with the other descriptive term, 'dermatitis'. Eczema (dermatitis) describes a clinical and histological pattern, which can be acute or chronic and has several causes. Acutely, epidermal oedema (spongiosis) and intra-epidermal vesiculation (producing multilocular blisters) predominate, whereas with chronicity there is more epidermal thickening (acanthosis). Vasodilatation and T-cell lymphocytic infiltration of the upper dermis also occur.

Clinical features

There are several patterns of eczema (Box 26.17) but the clinical features are similar, irrespective of the cause (Box 26.18). Some subtypes of eczema have specific distinguishing features, and these are discussed in more detail below.

Investigations

Bacterial and viral swabs for microscopy and culture are important in suspected secondary infection. Bacterial swabs are commonly positive, particularly for staphylococci, although clinical assessment is required to ascertain whether swab results are of clinical significance and whether antibiotic treatment is required. Individuals with atopic eczema have an increased susceptibility to herpes simplex virus (HSV) and are at risk of developing a widespread infection, eczema herpeticum. The presence of small, punched-out lesions on a background of worsening eczema suggests the possibility of secondary HSV infection. Skin scrapings to rule out secondary fungal infection should also be considered. Total IgE and specific IgE tests and skin prick tests are not routinely undertaken in atopic eczema as they are not usually helpful, although they may occasionally be indicated in some cases as directed by the history. Patch tests should be performed if contact allergic dermatitis is suspected (see Box 26.22 below). Skin biopsy is not usually required unless there is diagnostic doubt.

Management

A general approach to the management of eczema includes advice, education and support, required for patients with eczema of any type (Fig. 26.32). Input from patient support groups, such as the National Eczema Society in the UK, can be very helpful. Intensive and prolonged treatments are often required, and chronic eczema can have a major and devastating adverse impact on personal and family lives. Emollients and topical glucocorticoids are mainstays of treatment for all eczema types, to improve skin barrier function, limit transepidermal water loss and reduce inflammation. Emollients can be used as bath additives and soap substitutes, and applied directly to the skin, often combined with antiseptics. Sedative antihistamines are useful if sleep is interrupted but non-sedating antihistamines are ineffective, as itch in eczema is not primarily mediated by histamine.

Ointments are preferred for chronic eczema, whereas cream- or lotion-based treatment may be more appropriate for acute eczema (see Box 26.11). Treatment is once to twice daily. Hydrocortisone (1%) or clobetasone butyrate is generally used on the face, with more potent glucocorticoids restricted to trunk and limbs (see Box 26.12). A good strategy is to employ an intensive regimen with more potent glucocorticoids initially and then taper use according to response. A key principle is to use the least potent glucocorticoid that is effective for the shortest possible time. The patient should be given instructions on how much to apply, using the fingertip unit for guidance (a strip of glucocorticoid cream on distal phalanx pulp should cover two palm-size areas). It is also important to monitor glucocorticoid use and the easiest way to do this is ask the patient how long it takes them to use a specific size of glucocorticoid tube. The side-effects of topical glucocorticoid therapy need to be considered but glucocorticoid phobia and under-treatment of eczema are often more of a problem than over-treatment. Particular care should be taken on certain sites, such as the face and flexures, and in children and older adults (see Box 26.2 and Fig. 26.10).

The clinical features of eczema influence the choice of topical treatment. For example, appropriate treatment of acute exudative eczema could be with potassium permanganate soaks, emollients and topical glucocorticoids under wet wraps. Chronic eczema may be best treated with a potent topical glucocorticoid in an ointment formulation and occlusion with a paste bandage to ease itching and scratching.

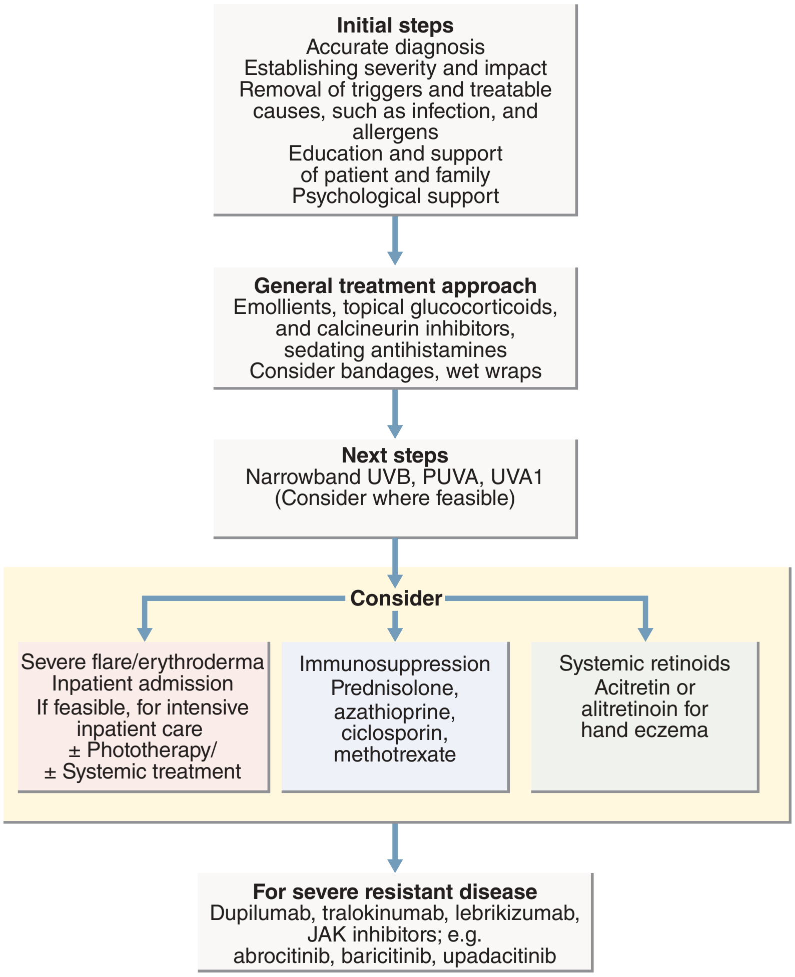
i 26.18 The clinical morphology of eczema

Acute

- Erythema, oedema, typically ill defined
- Papules, vesicles and occasionally bullae
- Exudation, fissuring
- Scaling

Chronic

- May be as above but less oedema, vesiculation and exudate
- Lichenification: skin thickening with pronounced skin markings, secondary to chronic rubbing and scratching
- Fissures (definition: slit-shaped deep ulcers), excoriations
- Dyspigmentation: hyper- and hypopigmentation can occur



Initial steps
Accurate diagnosis
Establishing severity and impact
Removal of triggers and treatable causes, such as infection, and allergens
Education and support of patient and family
Psychological support
General treatment approach
Emollients, topical glucocorticoids, and calcineurin inhibitors, sedating antihistamines
Consider bandages, wet wraps
Next steps
Narrowband UVB, PUVA, UVA1
(Consider where feasible)
Consider
Severe flare/erythroderma
Inpatient admission
If feasible, for intensive inpatient care
± Phototherapy/
± Systemic treatment
Immunosuppression
Prednisolone, azathioprine, ciclosporin, methotrexate
Systemic retinoids
Acitretin or alitretinoin for hand eczema
For severe resistant disease
Dupilumab, tralokinumab, lebrikizumab, JAK inhibitors; e.g. abrocitinib, baricitinib, upadacitinib

Fig. 26.32 General management approaches: atopic eczema. (JAK = Janus kinase; PDE = phosphodiesterase; PUVA = psoralen-ultraviolet A; UVA1 = ultraviolet A1; UVB = narrowband ultraviolet B)

The topical calcineurin inhibitors tacrolimus and pimecrolimus may be useful glucocorticoid-sparing agents for eczema, particularly on the face; they cause local cutaneous immunosuppression. Initial burning and stinging may limit use but are usually transient side-effects. Bacterial and viral skin infection risk may be increased due to immunosuppression. Caution should be employed with sun exposure and these agents should not be used in combination with phototherapy because of their immunosuppressive effects.

Atopic eczema

This is the most common subtype of eczema. The prevalence has increased dramatically since the early 1980s, and the disease now affects at least 20% of schoolchildren and 5%–10% of adults in the UK.

Pathogenesis

Generalised prolonged hypersensitivity to common environmental antigens, such as pollen and house-dust mite, is the hallmark of atopy, in which there is a genetic predisposition to produce excess IgE. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. Genetic factors play an important role in all these diseases, supported by higher concordance of atopic disease in monozygotic twins compared with dizygotic twins. Filaggrin gene mutations increase the risk of developing atopic eczema by more than threefold, emphasising the importance of epidermal barrier impairment in this disease. Other genes are also likely to be implicated, with many other susceptibility loci identified, although these studies require further replication. Decreased skin barrier function may also allow greater penetration of allergens through the epidermis, and thus cause immune stimulation and subsequent inflammation. The interaction between genes and environment is important; it has been estimated that 60%–80% of individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair. Eczema is characterised by infiltration of Th2 cells, which are known to play a role in activating mast cells and eosinophils, as well as stimulating IgE production by IgE-producing B cells. The therapeutic inhibition of IL-4 and IL-13, phosphodiesterase-4 and JAK pathways, highlights the involvement of these targets in atopic dermatitis pathogenesis. Emerging therapeutic targets for atopic eczema both in terms of targeting Th2-driven inflammation and skin barrier dysfunction is a rapidly evolving field and further informs our understanding at a mechanistic level (see Fig. 26.11). The contributing roles of the microbiome are also being explored. Thus, the pathogenesis of atopic eczema is complex and multifactorial, involving an interplay of contributing factors.

Clinical features

Atopic eczema is extremely itchy and scratching accounts for many of the signs (Fig. 26.33). Widespread cutaneous dryness (also known as xeroderma or xerosis) is another feature. The distribution and character of the rash vary with age (Box 26.19). Complications are listed in Box 26.20.

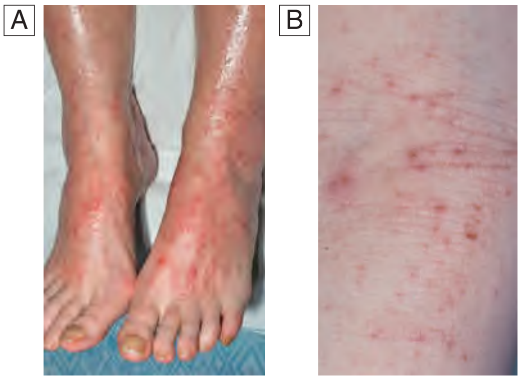


Fig. 26.33 Atopic eczema. **A** This patient had life-long chronic atopic eczema and experienced a generalised flare of disease triggered by infection. **B** Lichenification of chronic flexural eczema secondary to rubbing and scratching.

26.19 Atopic eczema: distribution and character of rash

Babies and infants

- Often acute and facial involvement prominent
- Trunk involved but nappy area usually spared

Children

- Flexures: behind knees, antecubital fossae, wrists and ankles

Adults

- Face and trunk usually involved, limb involvement not restricted to flexures
- Lichenification common

26.20 Complications of atopic eczema

Secondary infection

Bacterial

- *Staphylococcus aureus* most common

Viral

- Herpes simplex virus can cause a widespread severe eruption – eczema herpeticum
- Papillomavirus and molluscum contagiosum are more common in atopic eczema, especially if treated with topical glucocorticoids

Increased susceptibility to irritants

- Defective barrier function

Increased susceptibility to allergy

- Food allergy – mainly relevant in infants; eggs, cow's milk protein, nuts, fish, wheat and soya may cause an immediate reaction with angioedema and/or urticaria rather than exacerbation of eczema
- Anaphylaxis in severe allergy
- Increased risk of sensitisation to type IV allergens because of impaired barrier function

Impact on life and health

- Poor sleep, loss of schooling, behavioural difficulties, failure to thrive in children
- Impact on sleep, work, relationships, hobbies, psychology and quality of life in adults

Investigations

The diagnosis of atopic eczema is made using clinical criteria (Box 26.21). Interestingly, while most patients with atopic eczema have raised total IgE levels and IgE-specific antibodies, this is not a prerequisite for the diagnosis, as a significant minority have normal levels of IgE.

Management

The general principles of management are as described in Figure 26.32. Emollients and topical glucocorticoids, tar and ichthammol paste bandages, or wet wraps in children, are often required and are mainstays in improving barrier function and reducing inflammation, although they have not been shown to have a preventative effect against the subsequent development of atopic eczema when used in babies. Topical calcineurin inhibitors may be used as glucocorticoid-sparing agents but should not be used in infected eczema. Secondary infection should be treated but positive skin swabs in isolation, without clinical evidence of infection, do not necessarily require treatment with antibiotics, although antiseptics would be appropriate. Sedating antihistamines may help to break the itch/scratch cycle. Identification and avoidance of allergens are important.

Phototherapy is generally the next step, if topical therapies are insufficient (see Fig. 26.32). Narrowband UVB is usually the initial phototherapy of choice and can also be used in children. PUVA or UVA1 can also be

26.21 Diagnostic criteria for atopic eczema

Itchy skin rash (or history of itch or rubbing from parent) and at least three of the following:

- History of involvement of skin creases (or cheeks if < 4 years)
- History of atopic disease (asthma, hay fever) (or in a first-degree relative if < 4 years)
- Dry skin (xeroderma)
- Visible flexural eczema (cheeks, forehead, outer limbs if < 4 years)
- Onset in first 2 years of life

used if UVB is ineffective, although mainly in adults as PUVA is generally avoided in children. Localised phototherapy may be used for eczema on hands and feet and PUVA may be more effective in that situation. Systemic immunosuppression with, for example, oral glucocorticoids, intermittent ciclosporin, methotrexate or azathioprine may be needed if the response to topical therapies and phototherapy is inadequate. Systemic retinoids, such as acitretin or alitretinoin, may be indicated, for example, in hand and foot eczema.

Dupilumab, which blocks the IL-4 receptor alpha chain subunit common to both IL-4 and IL-13 receptors, is licensed for clinical use in patients with moderate-to-severe atopic dermatitis (600 mg by subcutaneous (SC) injection initial dose, followed by 300 mg SC two-weekly), as are the JAK inhibitors baricitinib, abrocitinib and upadacitinib. The anti-IL-13 agents tralokinumab (same dosing regimen as dupilumab) is also now approved for clinical use and lebrikizumab (500 mg SC two weekly for two doses and then 250 mg SC two-weekly and maintained at 250 mg SC four-weekly after 16 weeks) and phosphodiesterase-4 inhibitors and other therapeutic targets are showing promise in clinical trials (see Fig. 26.11).

Seborrhoeic eczema

This is an erythematous scaly rash affecting the scalp (dandruff), central face, nasolabial folds, eyebrows, central chest and upper back. It is associated with, and may be due to, overgrowth of *Malassezia* yeasts. When severe, it may resemble psoriasis. Severe or recalcitrant seborrhoeic eczema can be a marker of immunodeficiency, including HIV infection. Topical azoles, such as ketoconazole shampoo and cream, often combined with mild glucocorticoid, are mainstays. Treatment often needs to be repeated due to disease recurrence. Itraconazole may be considered for treatment-resistant disease.

Discoid eczema

Discoid eczema, which is also known as nummular eczema, is common and characteristically consists of discrete, coin-shaped eczematous lesions, which are often impetiginised and most commonly occur on the limbs of men. It is an eczema type that can be due to any chronic itchy condition, whether primarily of the skin or secondary to an underlying disease. Initial management should include topical antiseptics, in addition to emollients and topical glucocorticoids. Judicious antibiotic use may also be required for acute flares.

Irritant eczema

Detergents, alkalis, acids, solvents and abrasives are common irritants. Strong irritants have acute effects, whereas weaker irritants commonly cause chronic eczema, especially of the hands, after prolonged exposure. Individual susceptibility varies and older adults, atopic and light-skinned individuals are predisposed. Irritant eczema accounts for most occupational cases of eczema and is a significant cause of time off work. Irritant avoidance, including protective clothing (such as gloves), is essential. Emollients and topical glucocorticoids are indicated.

26.22 Common type IV delayed hypersensitivity allergens

Allergen	Source
Nickel	Jewellery, jean studs, bra clips, watches
Dichromate	Cement, leather, matches
Rubber chemicals	Clothing, shoes, rubber gloves, tyres
Colophony	Sticking plaster, collodion, nail varnish
Paraphenylenediamine	Hair dye, clothing, tattoos
Balsam of Peru	Perfumes, citrus fruits, shower/bath products
Neomycin, benzocaine	Topical medications
Parabens	Preservative in cosmetics and creams
Wool alcohols	Lanolin, cosmetics, creams
Epoxy resin	Resin adhesives, glues
Methyl- and chloromethyl-isothiazolinone	Preservatives, with frequent reports of allergy
Sesquiterpene lactone	Asteracea/compositae plants
Compositae mix	Asteracea/compositae plants

Allergic contact eczema

This occurs due to a delayed hypersensitivity reaction following contact with antigens or haptens. Previous allergen exposure is required for sensitisation, and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 26.22.

Allergy persists indefinitely and eczema occurs at sites of allergen contact and can secondarily spread beyond this. The distribution of eczema can be very informative regarding possible culprits. There are many recognisable patterns of sites of eczema involvement, such as earlobes, wrists and umbilicus due to contact with nickel in earrings, watches and jeans studs; hands and wrists due to rubber gloves; and upper eyelids due to colophony from rubbing of the eyes in nail varnish wearers. Oedema may also be a feature (Fig. 26.34). Allergen avoidance is key and may involve a change of occupation, recreational activities or hobbies. It is important to ensure that patients are fully informed as to the nature and likely occurrence of allergens and good detective work is required to scrutinise lifestyle and daily activities. Treatment with emollients and topical glucocorticoids helps but will not suffice if there is continued allergen exposure.

Asteatotic eczema

This occurs in dry skin and is common in older adults. Low humidity caused by central heating, over-washing, diuretics and cholesterol-lowering drugs predispose. The most common site is the lower legs, and a 'crazy paving' pattern of fine fissuring on an erythematous background is seen. Emollients are a mainstay, in combination with topical glucocorticoids. Patients must be advised to use caution with flammable emollients and to avoid bathroom slippages related to emollients on floor and feet, and this is particularly relevant for older individuals.

Gravitational eczema

Gravitational or stasis eczema occurs on the lower legs and is often associated with signs of venous insufficiency: oedema, loss of hair, induration, lipodermatosclerosis and ulceration. Emollients are important and topical glucocorticoids should be applied to eczematous areas but not to ulcers. There is a high risk of sensitisation to topical preservatives (such as chlorocresol), antibiotics (such as neomycin) and bandages (such as rubber additives). Oedema and ulceration are treated by leg elevation and compression bandages.

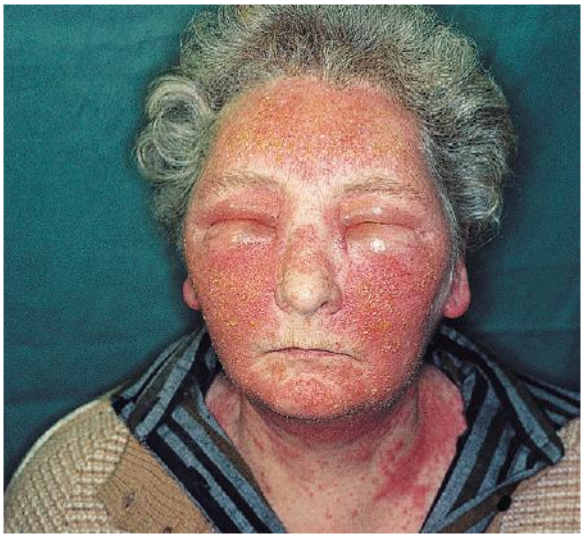

Fig. 26.34 **Allergic contact eczema.** This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral periorbital oedema are typical.

Lichen simplex

Lichenification of eczema occurs secondary to chronic rubbing and scratching, and lichen simplex is a localised form. Common sites include the neck, lower legs and anogenital region. Treatment with emollients and very potent topical glucocorticoids may be required, often impregnated in tape or with occlusion.

Pompholyx

Intensely itchy vesicles and bullae occur on the palms, palmar surface and sides of the fingers and soles. Pompholyx may have several causes, which include atopic eczema, irritant and contact allergic dermatitis and fungal infection. The underlying cause must be treated or removed.

Psoriasis and other erythematous scaly eruptions

Psoriasis

Psoriasis is a chronic inflammatory, hyperproliferative skin disease. It is characterised by well-defined, erythematous scaly plaques, particularly affecting extensor surfaces, scalp and nails, and usually follows a relapsing and remitting course. Psoriasis affects approximately 1.5%–3% of populations of European ancestry but is less common in Asian, South American and African populations. It occurs equally in both sexes and at any age; although it is uncommon under the age of 5 years, more than 50% of patients present before the age of 30 years. The age of onset follows a bimodal distribution, with an early-onset type in the teenage or early adult years, often with a family history of psoriasis, a more severe disease course and strong HLA association. The later-onset type is typically seen between 50 and 60 years, usually without a family history and with a less severe disease course.

Pathogenesis

Both genetic and environmental factors are important. Twin studies show concordance rates of 60%–75% and 15%–20% for psoriasis arising in monozygotic and dizygotic twins, respectively. The age at onset and severity of disease are often similar in familial cases. If one parent has psoriasis, the chance of a child being affected is about 15%–20%; if both parents have the disease, this rises to 50% and the risk is increased further if a sibling also has the disease.

26.23 Exacerbating factors in psoriasis

Trauma

- Lesions can appear at sites of skin trauma, such as scratches or surgical wounds (Köbner isomorphic phenomenon)

Infection

- β-Haemolytic streptococcal throat infections often precede guttate psoriasis (see Fig. 26.36C)
- Severe psoriasis may be the initial presentation of HIV infection

Sunlight

- Psoriasis may occur or worsen after sun exposure, mainly due to Köbnerisation at sites of sunburn or polymorphic light eruption

Drugs

- Antimalarials, β-adrenoceptor antagonists (β-blockers), lithium, NSAIDs and TNF-α inhibitors can exacerbate psoriasis
- 'Rebound' flare of psoriasis may occur after withdrawal of systemic glucocorticoids or potent topical glucocorticoids. Rebound psoriasis is often unstable and may be pustular

Psychological factors

- Anxiety and stress may exacerbate psoriasis in predisposed individuals

(HIV = human immunodeficiency virus; NSAIDs = non-steroidal anti-inflammatory drugs; TNF-α = tumour necrosis factor alpha)

Variants of the HLA-C region within the major histocompatibility complex (MHC) on chromosome 6 account for almost half of the heritability of psoriasis. However, at least 70 other loci are implicated, with susceptibility variants that lie within or close to genes involved in regulating epidermal barrier function, antigen presentation, cytokine production, notably IL-13 and IL-23, T-cell differentiation (especially Th1 and Th17 subsets) and nuclear factor kappa B (NFκB) signalling. Some of the loci that predispose to psoriasis overlap with those implicated in Crohn disease, ankylosing spondylitis and psoriatic arthritis.

Environmental triggers for psoriasis are shown in Box 26.23. Although the theory is controversial, stress may exacerbate psoriasis in susceptible individuals and psoriasis is itself a cause of psychological stress. Likewise, there is a higher incidence of smoking and heavy alcohol consumption in patients with psoriasis, but it is unclear whether this is cause or effect. There is also an association between psoriasis and metabolic syndrome.

The histological changes of psoriasis are shown in Figure 26.35. The main features are:

- keratinocyte hyperproliferation and abnormal differentiation, leading to retention of nuclei in the stratum corneum
- inflammation, with a T-cell (mainly activated Th1 and Th17) lymphocytic infiltrate and release of cytokines and adhesion molecules, such as interleukins (including IL-17, IL-23 and IL-12), TNF-α, IFN-γ and intercellular adhesion molecule (ICAM)-1
- vascular changes, with tortuosity of dermal capillary loop vessels and release of mediators, such as vascular endothelial growth factor (VEGF).

The initiating event for psoriasis is unknown. Disordered cell proliferation is a key feature; this was previously thought to be the primary event but is now considered to be secondary to inflammatory change. The transit time for keratinocyte migration, from basal layer to shedding from stratum corneum, is shortened from approximately 28 to 5 days, so that immature cells reach the stratum corneum prematurely. Proliferation rate is also increased in non-lesional skin but to a lesser extent. Similarly, even the clinically unaffected nails of patients with psoriasis grow more quickly than those of controls.

Upper dermal T-lymphocyte infiltrate

Fig. 26.35 The histology of psoriasis.

While immunological factors clearly play a key role in psoriasis, the precise mechanisms of disease initiation and the sequence of events that lead to psoriasis are not fully defined. Therapeutic efficacy through targeted biological inhibition of the effects of key cytokines, notably TNF-α IL-17, IL-23 and IL-12, continues to provide major insight into the pathogenesis of psoriasis and the pathways and mechanisms involved.

Clinical features

Psoriasis has several different presentations (Fig. 26.36).

Plaque psoriasis

This is the most common presentation and usually represents more stable disease. The typical lesion is a raised, well-demarcated erythematous plaque of variable size (see Fig. 26.36A). In untreated disease, silver/white scale is evident and more obvious on scraping the surface, which reveals bleeding points (Auspitz sign). The most common sites are the extensor surfaces, notably elbows and knees, and the lower back. Others include:

- *Scalp*: involvement is seen in approximately 60% of patients (see Fig. 26.36E). Typically, easily palpable, erythematous scaly plaques are evident within hair-bearing scalp and there is clear demarcation at or beyond the hair margin. Occipital involvement is common and difficult to treat. Less often, fine diffuse scaling may be present and difficult to distinguish from seborrhoeic dermatitis. Involvement of other 'seborrhoeic sites', such as eyebrows, nasolabial folds and the pre-sternal area, is not uncommon and again may be confused with seborrhoeic dermatitis. Temporary hair loss can occur but permanent loss is unusual.
- *Nails*: involvement is common, with 'thimble pitting', onycholysis (separation of the nail from the nail bed, see Fig. 26.36B), subungual hyperkeratosis and periungual involvement.
- *Flexures*: psoriasis of the natal cleft and submammary and axillary folds is usually symmetrical, erythematous and smooth, without scale.
- *Palms*: psoriasis of the palms can be difficult to distinguish from eczema.

Guttate psoriasis

This is most common in children and adolescents and is often the initial presentation (see Fig. 26.36C). It may present shortly after a streptococcal throat infection and evolves rapidly. Individual lesions are droplet-shaped, small (usually less than 1 cm in diameter), erythematous, scaly and numerous. An episode of guttate psoriasis may clear spontaneously or with topical treatment within a few months, but UVB phototherapy is often required and is highly effective. Guttate psoriasis often heralds the onset of plaque psoriasis in adulthood.

Erythrodermic psoriasis

Generalised erythrodermic psoriasis is a medical emergency (see Fig. 26.36D).

Pustular psoriasis

Pustular psoriasis may be generalised or localised. Generalised pustular psoriasis is uncommon, unstable and life-threatening. It will often emerge in the context of plaque disease and the onset is usually sudden, with large numbers of small, sterile pustules on an erythematous background, often merging into sheets, with waves of new pustules in subsequent days. The patient is usually febrile and systemically unwell, and this must be dealt with as a medical emergency. Unstable pustular psoriasis may be precipitated as a rebound phenomenon following either topical or systemic glucocorticoid use in a patient with psoriasis. Localised pustular psoriasis of the palms and soles (palmoplantar pustulosis) is more common, chronic and closely associated with smoking; small, sterile pustules and erythema develop and resolve with pigmentation and scaling. A localised form of sterile pustulosis of a few digits (acropustulosis) can also occur. It is unclear whether these localised forms of pustulosis are truly psoriatic.

Arthropathy

Approximately one in four individuals with psoriasis develop an inflammatory arthropathy, which can take on several patterns. Joint involvement is more likely in patients with psoriatic nail disease. Psoriatic arthritis is discussed in more detail in Chapter 25.

Investigations

Skin biopsy is not usually required but may be performed if there is diagnostic doubt. An infection screen, particularly throat swab and/or serology for recent streptococcal infection, may be informative in guttate psoriasis. Assessment of impact on life using the DLQI and disease severity and extent using PASI (Psoriasis Area and Severity Index) are essential to determine disease severity and impact objectively and are employed as tools to determine access to biologic therapies. Due to the association of psoriasis with metabolic syndrome, comorbidities and cardiovascular risk factors should be assessed and managed along usual lines. HIV testing should be considered in severe or recalcitrant psoriasis.

Management

Counselling about diagnosis and management of skin involvement and other comorbidities is paramount. Information and services must be available for patients. Psoriasis can have a major impact on all aspects of life, and this must not be under-estimated. Reassurance is also needed, as the condition is generally not life-threatening. Advice regarding reduction in risk factors for cardiovascular disease should be given (smoking cessation, reduction of alcohol intake, adequate exercise and a normal body mass index). Associated diseases, such as hypertension and diabetes, should be treated.

Patients need to be involved in their own management, as the disease is usually chronic, and the benefit/risk profile of treatments must be discussed and tailored to individuals. The endpoint for treatment also needs to be discussed because complete disease clearance may not be practical or appropriate and patients vary considerably in their treatment requirements. Extent of disease and impact on quality of life must

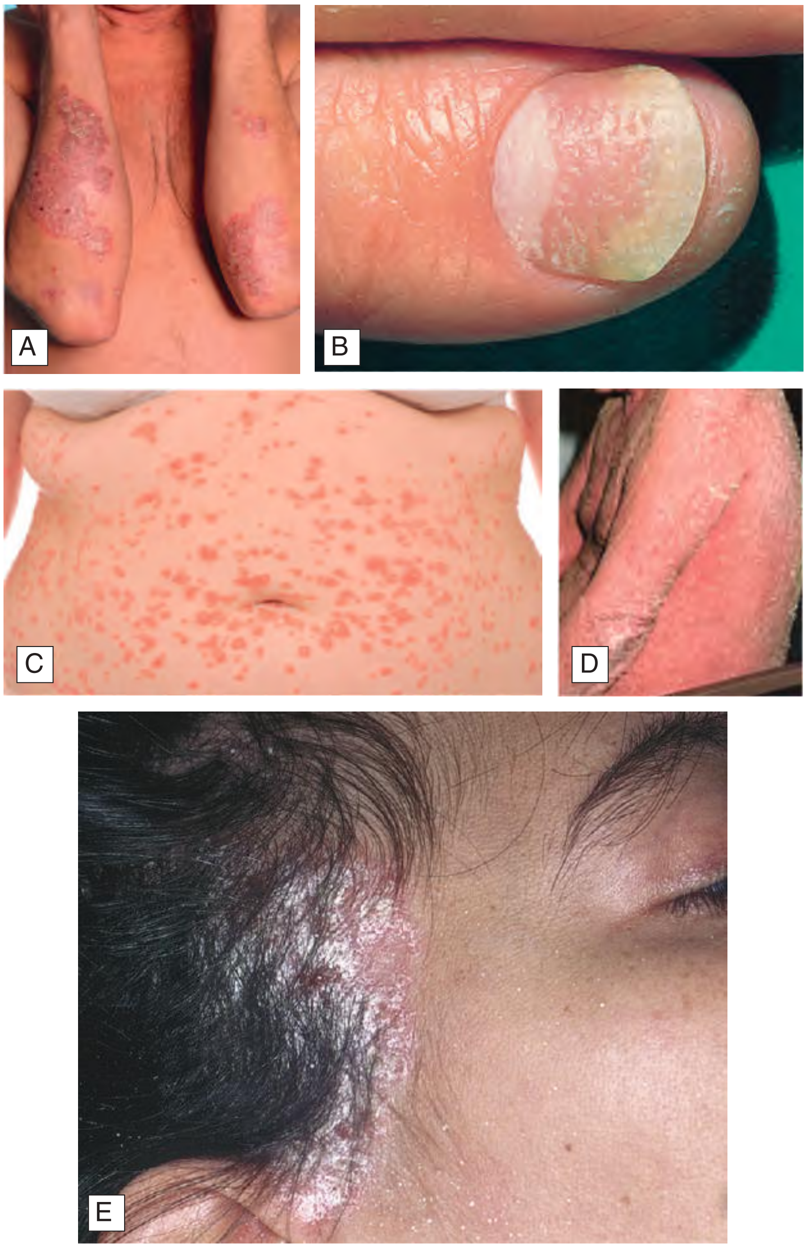

Fig. 26.36 **Psoriasis.** **A** Chronic plaque psoriasis, most prominent on extensor surfaces. **B** Nail involvement, with coarse pitting and separation from the nail plate (onycholysis). **C** Guttate psoriasis following a streptococcal throat infection. **D** Erythrodermic psoriasis. **E** Psoriasis on the scalp. *(E) From Wilson SF, Giddens JF. Health assessment for nursing practice. 7th ed. Elsevier; 2022.*

be considered. Patient adherence to topical and systemic therapies is essential and dependent on treatment practicalities.

The treatment approach generally follows a stepwise progression, with treatment categories broadly summarised (Fig. 26.37).

Topical treatments, including emollients, are the first-line approach. Vitamin D receptor agonists, such as calcipotriol, calcitriol and tacalcitol, are often used as first-line topical treatment. The mechanism of action includes increased differentiation and reduction of proliferation, reducing plaque scale and thickness. Calcipotriol is most widely used and can be applied once to twice daily; if less than 100g of ointment is used each week, there is no risk of hypercalcaemia. Vitamin D analogues can cause irritation, but this is often temporary. Topical glucocorticoids may be required in the management of psoriasis, particularly at flexural or facial sites, and may be alternated or combined with vitamin D analogues. However, safe, appropriately supervised and judicious use is necessary, with awareness of the potential risk of rebound unstable or pustular psoriasis with glucocorticoid over-use or sudden cessation. Dithranol and coal tar are effective and, like vitamin D analogues, work by increasing differentiation and inhibiting proliferation. Although often effective, they are messy and time-consuming. Modified versions of the Goeckerman regimen (the combination of coal tar and UVB) are still occasionally used, but coal tar has a characteristic odour and can be irritant. Short-contact dithranol therapy at relatively high concentrations applied for 15–30 minutes can be used but causes brown staining of skin and purple discoloration of light hair. In recent years, efforts have been made to improve the tolerance of tar and dithranol preparations, but at reduced efficacy. Overall, the use of tar and dithranol has markedly reduced in recent years but they can be highly effective in selected patients.

If topical treatment is insufficient, then UVB phototherapy or PUVA should usually be the next step. If the patient continues to have active disease or early recurrence, then the addition of systemic retinoid, such as acitretin, to UVB or PUVA can be effective. Alternatively, immunosuppressants, such as methotrexate or ciclosporin, may be required. If these approaches do not provide adequate control, fumaric acid esters, apremilast and biologics should be considered and biologic therapies are

now widely used in routine dermatology practice and have had a major impact on the management of patients with severe or poorly responsive psoriasis and are now increasingly used at an earlier stage in the disease process (see Fig. 26.11).

The active component of fumaric acid ester therapy is dimethyl fumarate and efficacy in psoriasis is established. Common adverse effects are flushing and diarrhoea. Lymphopenia is also expected at effective doses. Apremilast (a phosphodiesterase-4 inhibitor) is indicated for moderate to severe psoriasis resistant to standard measures (such as light-based therapies, methotrexate or ciclosporin). Of the biologic agents, the anti-TNF-α agents (adalimumab, etanercept, infliximab, certolizumab), ustekinumab (an inhibitor of IL-12 and IL-23), guselkumab, risankizumab and tildrakizumab (IL-23 inhibitors), and secukinumab, ixekizumab, bimekizumab and brodalumab (IL-17 inhibitors) may all offer high levels of efficacy. There is also growing interest and application of JAK inhibitors in psoriasis, and whilst tofacitinib and upadacitinib are approved for use in psoriatic arthritis, deucravacitinib (tyrosine kinase 2 (TYK2) inhibitor) is approved by NICE for use in skin psoriasis, although caution remains regarding use of JAK inhibitors in the elderly, particularly regarding thromboembolic risk. Based on a recent Cochrane review, infliximab, bimekizumab, ixekizumab and risankizumab are the most effective therapies for achieving PASI-90 in people with moderate-to-severe psoriasis. Interestingly, IL-36 inhibitors (spesolimab and imsidolimab) are also showing great promise in early clinical trials in generalised pustular psoriasis.

Irrespective of the treatment chosen, individualised management is essential. For example, a patient with localised plaque psoriasis on elbows, knees and sacrum should respond to topical treatment only, whereas someone with guttate psoriasis is likely to need phototherapy as a first-line approach because of difficulties in topical drug application in extensive disease. A patient with extensive chronic plaque psoriasis and significant arthropathy would be better suited to a systemic drug, such as methotrexate or a biologic, than phototherapy, which would be unlikely to improve joint symptoms. Thus, whilst a stepwise general approach to management (see Fig. 26.37) may offer guidance, the correct choice for any given patient must be determined on an individual basis.

Pityriasis rosea

This is an acute, self-limiting exanthem that particularly affects young adults and occurs worldwide, with a slight female predominance. It usually presents in spring and summer, although no infective agent has been identified and its aetiology is unknown. It is characterised by the appearance of a ‘herald patch’, an oval lesion (1–2 cm) with a pinkish (salmon-coloured) centre, a darker periphery and a characteristic collarette of scale. It is followed one to two weeks later by a widespread papulosquamous eruption, which is typically arranged in a symmetrical ‘fir tree’ pattern on the trunk. Individual lesions also have a collarette of scale. An inverse variant with flexural involvement can occur. Mucosal involvement is rare. There is a small risk of recurrence. Symptomatic relief can be achieved with emollients and mild topical glucocorticoids. Post-inflammatory hyperpigmentation can supervene, particularly in darker skin types.

Pityriasis lichenoides chronica

This is rare but typically presents within the first three decades of life. The aetiology is unclear, but the condition is part of a spectrum and remits spontaneously. The more acute variety (pityriasis lichenoides et varioliformis acuta, PLEVA) presents as crops of papules that rapidly evolve with central necrosis, each attack lasting up to three months. The more chronic variety presents as a persistent, widespread, scaly eruption. Characteristically, lesions are brown papules with a mica-like scale (‘cornflake’). The condition fluctuates but can persist for months or years. Emollients, topical glucocorticoids and long-term oral erythromycin can occasionally be helpful. UVB phototherapy or PUVA is usually effective, although recurrences are high.

Drug eruptions

It is essential to consider a drug cause in anyone presenting with an erythematous maculopapular or papulosquamous eruption, and a careful drug history is critical. Exfoliation (‘peeling’) and post-inflammatory hyper- or, less commonly, hypopigmentation can occur.

Other causes

Secondary syphilis, pityriasis versicolor and tinea corporis fungal infection can all cause an erythematous papulosquamous rash and must be considered in the differential diagnosis of erythematous papulosquamous rashes.

Lichenoid eruptions

Lichen planus

Lichen planus occurs worldwide. It typically presents as a pruritic rash; the mucosae, hair and nails may also be involved.

Pathogenesis

The disease probably has an autoimmune basis since there is an association with inflammatory bowel disease, primary biliary cholangitis, autoimmune hepatitis, hepatitis B and C, alopecia areata, myasthenia gravis and thymoma. There are also similarities with graft-versus-host disease (GVHD). Lichen planus can occasionally occur in families and possible HLA associations have been reported but there is no clear inheritance pattern. On skin biopsy, characteristic histological changes include hyperkeratosis, basal cell degeneration and a heavy, band-like T-lymphocyte infiltrate in the papillary dermis, with affinity for the epidermis (epidermotropism). The dermo-epidermal junction has a 'sawtooth' appearance.

Clinical features

Lichen planus occurs in both sexes and at any age, although usually between 30 and 60 years. It generally presents on the distal limbs, most commonly on the flexural aspects of the wrists and forearms (Fig. 26.38), and on the lower back. It is intensely itchy, and lesions are violaceous, shiny, flat-topped, polygonal papules, with a characteristic fine lacy, white network on the surface (Wickham striae). New lesions may appear at sites of skin trauma (Köbner phenomenon) (see Fig. 26.38) and the rash may become generalised. Individual lesions may last for many months and can become hypertrophic and modified by scratching, particularly on the lower legs. The eruption usually remits over months but can become chronic, particularly with hypertrophic disease. Post-inflammatory pigmentary change is common, particularly in darker skin types. Mucous membrane involvement occurs in 30%–70% of patients, usually as a network of white, lacy striae on the buccal mucosae and tongue. These oral changes are often asymptomatic and should be sought on examination. Genital and other mucosal surfaces can also be affected. Nail involvement occurs in about 10% and can range from longitudinal ridging to a destructive nail dystrophy, scarring (pterygium) and nail loss. Scalp involvement usually presents as an inflammatory scarring alopecia, often with tufting of residual hairs. The classical presentation of lichen planus is unmistakable, but less common atypical variants, which include annular, atrophic, actinic, linear, bullous, follicular, pigmented and ulcerative types, can be a diagnostic challenge.

Investigations

A skin biopsy should be performed if there is diagnostic doubt. A careful drug history must be taken, as, although the classical presentation of lichen planus is usually 'idiopathic', the main differential is a drug-induced lichenoid reaction (see below). Other differential diagnoses include psoriasis, pityriasis rosea, pityriasis lichenoides chronica and secondary syphilis. Screening for underlying disease, such as hepatitis, must be considered.

Management

The condition is usually self-limiting, although rarely it may persist for years, particularly oral lichen planus. Treatment is symptomatic and potent local glucocorticoids (topical, with occlusion or by injection for hypertrophic disease, or as oral rinse for oral involvement) may help the intense itch; short courses of systemic glucocorticoids are sometimes required for extensive disease. UVB, PUVA or UVA1 can be beneficial and, for recalcitrant disease, retinoids or immunosuppressants, such as ciclosporin or methotrexate, may be needed. A low but significant risk of malignant transformation exists with persistent oral and genital disease, so active treatment, surveillance and smoking cessation are important.

Drug-induced lichenoid eruptions

Drug-induced lichenoid reactions that are clinically and histologically difficult to distinguish from idiopathic lichen planus are important to identify. The likely culprits are gold, quinine, proton pump inhibitors, sulphonamides, penicillamine, antimalarials, antituberculous drugs, thiazide diuretics, β-adrenoceptor antagonists (β-blockers), angiotensin-converting enzyme (ACE) inhibitors, NSAIDs, sulphonylureas, lithium and dyes in colour developers (see Box 26.35).

Graft-versus-host disease

In the acute stage of graft-versus-host disease (GVHD), there is a distinctive dermatitis associated with hepatitis. After about three months, chronic GVHD can present with a lichenoid eruption on the palms, soles, face and upper trunk. Progressive sclerodermatous skin thickening, associated with pigmentary changes, may lead to contractures and limited mobility.

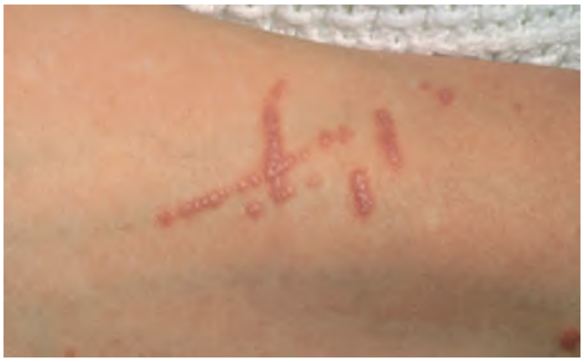

Fig. 26.38 Lichen planus. Violaceous papules on the flexural aspect of the forearm, arising at a site of minor linear trauma (Köbner phenomenon).

Urticaria

Urticaria ('hives') is caused by localised dermal oedema secondary to a temporary increase in capillary permeability. If oedema involves subcutaneous or submucosal layers, the term angioedema is used.

Clinical features

Acute urticaria may be associated with angioedema of the lips, face, tongue, throat and, rarely, wheezing, abdominal pain, headaches and even anaphylaxis. Urticaria present for less than six weeks is defined as acute, and chronic if it continues for more than six weeks. Individual weals (definition: evanescent discrete areas of dermal oedema, often centrally white due to masking of local blood supply by fluid; weals can be papules, macules, patches and plaques – Fig. 26.39) last for less than 24 hours; if they persist, urticarial vasculitis needs to be considered. Clarification of the duration of urticaria can be achieved by drawing around the weal and re-assessing 24 hours later. History-taking should probe for possible causes, including medications (Box 26.24). Physical triggers can also be assessed in challenge testing, such as eliciting dermographism or pressure testing. Enquiry about family history and medication, particularly ACE inhibitors, is important in angioedema. Examination may be unremarkable, or weals may be evident (see Fig. 26.39). The skin should be stroked firmly with an orange stick to ascertain whether dermographism is present.

Mast cell degranulation and release of histamine and other vasoactive mediators is the basis of urticaria (Fig. 26.40). Chronic spontaneous urticaria (previously called 'chronic idiopathic' or 'chronic ordinary' urticaria) is the most common chronic urticaria and has an autoimmune pathogenesis in some cases.

Investigations

Investigations should be guided by the history and possible causes, but are often negative, particularly in acute urticaria. Some, or all, of the following may be appropriate:

- *Full blood count*: eosinophilia in parasitic infection or drug cause.
- *Erythrocyte sedimentation rate (ESR) or plasma viscosity*: elevated in vasculitis.
- *Urea and electrolytes, thyroid and liver function tests, iron studies*: may reveal an underlying systemic disorder.
- *Total IgE and specific IgE to possible allergens*: shellfish, peanut, house-dust mite. Particularly relevant if there is angioedema.
- *Autoantibodies, particularly antinuclear factor*: positive in systemic lupus erythematosus (SLE) and often positive in urticarial vasculitis. Other autoimmune diseases, such as rheumatoid arthritis and autoimmune hepatitis or thyroid disease, may be associated.
- *Complement C3 and C4 levels*: if these are low due to complement consumption, *C1 esterase inhibitor* activity should be measured.
- *Infection screen*: hepatitis screen and HIV may be indicated.

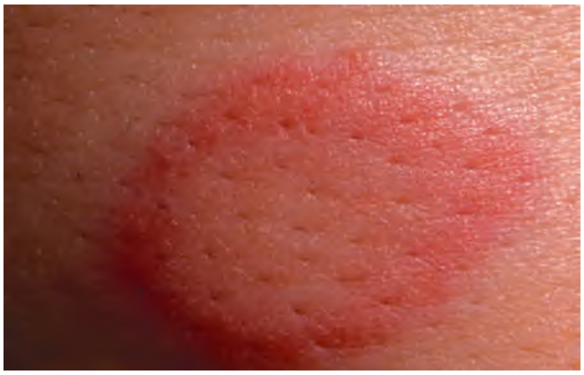

Fig. 26.39 Urticaria. Erythema, reflecting dilated dermal vessels, and oedema (with upper dermal oedema obscuring the erythema centrally) are evident. Note the absence of epidermal changes.

26.24 Causes of urticaria

Acute and chronic urticaria

- Autoimmune: due to antibodies that cross-link the IgE receptor on mast cells
- Allergens in foods and inhalants
- Contact allergens: latex, animal saliva
- Drugs: see Box 26.35
- Physical stimuli: heat, cold, pressure, sun, sweat, water
- Infections: intestinal parasites, hepatitis
- Others: SLE, pregnancy, thyroid disease
- Idiopathic: chronic spontaneous urticaria and angioedema

Urticarial vasculitis

- Hepatitis B, SLE, idiopathic

(IgE = immunoglobulin E; SLE = systemic lupus erythematosus)

- *Skin biopsy*: if urticarial vasculitis is suspected.
- *Challenge tests*: to confirm physical urticarias, such as dermographism, pressure, heat, cold.

Management

Removal or treatment of any trigger is essential, although is not identified in most cases. Urticaria may be precipitated by aspirin, NSAIDs, codeine and opioids, and it is advisable to suggest alternatives such as paracetamol. In chronic urticaria, non-sedating antihistamines, such as fexofenadine, loratadine or cetirizine, are usually beneficial. If there is lack of response after two weeks, an alternative non-sedating antihistamine should be used and an H_2-blocker, such as cimetidine or famotidine, can be added. Mast cell stabilisers or leukotriene receptor antagonists can be used for more recalcitrant disease, although concerns have been raised about neuropsychiatric adverse effects of montelukast, so caution is required. For chronic urticaria, narrowband UVB phototherapy is valuable and has proven efficacy. Systemic glucocorticoids are widely prescribed for urticaria but are not indicated in most cases. If systemic glucocorticoids are used, efficacy may be seen only at relatively high doses and they are appropriate only for occasional short courses in the acute setting, usually in association with angioedema. Patients with a history of life-threatening anaphylaxis, as in peanut or wasp sting allergy, should carry a self-administered adrenaline (epinephrine) injection kit. The management of anaphylaxis is discussed in Chapter 10 and the management of hereditary angioedema is discussed in Chapter 4. The anti-IgE monoclonal antibody omalizumab may be effective in patients with severe recalcitrant urticaria (see Fig. 26.40).

Bullous diseases

Blistering can occur at any level in the skin and there are a variety of different presentations, depending on the underlying defect and level of involvement. Knowledge of the molecular basis of many blistering disorders has advanced considerably through understanding of the basic processes of cell adhesion and studies of rare genetic blistering disorders, particularly epidermolysis bullosa (Box 26.25). This section concentrates on primary blistering skin diseases.

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is a medical emergency, as the extensive mucocutaneous blistering is associated with a high mortality rate. It is usually drug-induced (see Box 26.35), with anticonvulsants, sulphonamides, sulphonylureas, NSAIDs, allopurinol and antiretroviral therapy often implicated. Usually 1–4 weeks after drug commencement, the patient becomes systemically unwell and often pyrexial. Erythema and blistering develop, initially on the trunk but rapidly involving all skin; an early warning sign is cutaneous pain. Sheets of blisters coalesce and denude, and the underlying skin is painful and erythematous (Fig. 26.41). Gentle lateral pressure on stroking the skin results in epidermal detachment (Nikolsky sign), demonstrating the severity of skin fragility. Mucous membrane involvement and blistering are usual. Blistering of skin and mucosae may be haemorrhagic. A disease severity score (Box 26.26) is used to predict outcome. The main differential diagnosis is staphylococcal scalded skin syndrome, although the diagnosis is usually obvious in an adult patient with a culprit drug. There is often overlap with Stevens–Johnson syndrome (SJS), in which blistering targetoid lesions, especially on palms and soles, with mucosal involvement and systemic upset may be evident.

Full-thickness skin biopsy should be undertaken for histology and direct immunofluorescence to exclude immunobullous or other diagnoses. Identification and discontinuation of the causative drug is essential. Urgent immediate referral to dermatology and ophthalmology is required in suspected TEN/SJS as sepsis and multi-organ failure are major risks. Intensive care in a dedicated dermatology ward or intensive care or burns unit is of paramount importance. Treatment is supportive, with regular sterile dressings and emollients, careful attention to fluid balance and treatment of infection if it develops. Urethral and ocular involvement is common and must be looked for and treated symptomatically. Chronic sequelae, including ocular and urethral scarring and adverse psychological impact can be problematic in survivors. There is no conclusive evidence that intravenous immunoglobulins, systemic glucocorticoids or ciclosporin improve outcomes and survival.

Immunobullous diseases

There are various subtypes of immunobullous disease that affect patients of different ages and have clinical characteristics (Box 26.27). The key investigation is an elliptical biopsy taken from the edge of a recent blister (Box 26.28). The sample is halved: one half is put in formalin for subsequent histology, while the other is sent fresh for direct immunofluorescence. Serum should also be sent for indirect immunofluorescence in suspected immunobullous disease.

Bullous pemphigoid

Bullous pemphigoid (BP) is the most common immunobullous disease and occurs worldwide. It occurs in males and females equally and in older people, with an average age of onset of 65 years.

Pathogenesis

The disease is caused by autoantibodies (BP-230 and BP-180) directed against the hemi-desmosomal BP antigens BPAg-1 (intracellular) and BPAg-2 (transmembranous type XVII collagen), respectively. Antibody–antigen binding initiates complement activation and inflammation, with hemi-desmosomal damage and subepidermal blistering.

Clinical features

There is often a lengthy prodrome of an itchy, urticated, erythematous rash prior to the development of tense bullae (Fig. 26.42A). Milia

Fig. 26.40 Pathogenesis of urticaria. Mast cell degranulation occurs in a variety of ways. (1) Type I hypersensitivity causes degranulation. (2) Spontaneous mast cell degranulation in chronic urticaria. (3) Chemical mast cell degranulation. (4) Autoimmunity, with IgE antibodies directed against IgE receptors or IgE itself. Histamine and the leukotrienes are especially relevant mediators in urticaria. Heparin release is probably not a major factor in urticaria but plays a role in the osteoporosis that can occur in systemic mastocytosis. (IgE = immunoglobulin E; NSAIDs = non-steroidal anti-inflammatory drugs)

i 26.25 Classification of epidermolysis bullosa

Type	Mode of inheritance	Level of blister*	Abnormality
Simple	Autosomal dominant	Epidermal basal cell	Keratins 5 and 14
Junctional	Autosomal recessive	Lamina lucida	Laminin-5 and $\alpha_6\beta_4$ integrin
Dystrophic	Autosomal dominant and recessive	Dermis below lamina densa	Collagen VII

*See Figure 26.1.

(definition: small epidermal keratin cysts) may develop due to basement membrane disruption. Mucosal involvement is uncommon.

Investigations

The diagnosis can be made by skin biopsy, which shows subepidermal blistering with an eosinophil-rich inflammatory infiltrate. Direct immunofluorescence demonstrates the presence of IgG and C_3 at the basement membrane (Fig. 26.42B). Indirect immunofluorescence may show positive titres of circulating anti-epidermal antibodies. Distinction from epidermolysis bullosa acquisita requires immunofluorescence studies using the patient's serum on salt-split skin. In BP, the immunoreactants localise to the epidermal side (hemi-desmosome) of split skin, whereas in epidermolysis bullosa acquisita they localise to the base of the split (type VII collagen/anchoring fibrils).

Management

Very potent topical glucocorticoids are effective and may be sufficient in frail older patients; they need to be applied to all sites, however, and not just lesional skin. Tetracyclines, such as doxycycline, have important anti-inflammatory effects and may limit the use of systemic glucocorticoids. Doxycycline was shown to be non-inferior to prednisolone for initial control of bullous pemphigoid and to have fewer long-term adverse effects, although most patients with extensive disease will go on to require systemic glucocorticoids (0.75 mg/kg/day or less), often combined with immunosuppressants as glucocorticoid-sparing agents. In severe refractory disease, other therapies, such as intravenous immunoglobulin or rituximab, are sometimes used but are of unproven efficacy. The condition often burns out spontaneously over a few years.

Elsevier; 2012.*

26.26 The SCORTEN disease severity score for toxic epidermal necrolysis

Factor

- Age > 40 years
- Heart rate > 120 beats/min
- Cancer or haematological malignancy
- Involved body surface area > 10%
- Blood urea > 10 mmol/L (28 mg/dL)
- Serum bicarbonate < 20 mmol/L
- Blood glucose ≥ 14 mmol/L (252 mg/dL)

Mortality rates

- 0–1 factor present = 3%
- 2 factors = 12%
- 3 factors = 35%
- 4 factors = 58%
- ≥ 5 factors = 90%

From Bastuji-Garin S, Fouchard N, Bertocchi M, et al. SCORTEN: a severity-of-illness score for toxic epidermal necrolysis. J Invest Dermatol. 2000;115:149–153.

26.27 Age of onset in immunobullous skin disorders

Disease	Age
Pemphigus vulgaris	40–60 years
Pemphigus foliaceus	Any age (endemic form in parts of Brazil and South Africa, from adolescence on)
Bullous pemphigoid	Sixties and over
Dermatitis herpetiformis	Young, associated with coeliac disease
Linear IgA disease	Any age
Pemphigoid gestationis	Pregnant females
Epidermolysis bullosa acquisita	Any age
Bullous lupus erythematosus	Young females of African ancestry

Pemphigus

Pemphigus is less common than BP and patients tend to be younger.

Pathogenesis

The cause is IgG1 and IgG4 autoantibodies, directed against desmogleins-1 and -3, resulting in intra-epidermal blistering. The syndrome may occur spontaneously or be secondary to drugs such as penicillamine or captopril and underlying malignancy (paraneoplastic pemphigus). Pemphigus foliaceus is a very superficial form, in which antibodies are directed against desmoglein-1 only and affect just the most superficial epidermis.

Clinical features

Skin and mucosae are usually involved, although disease may be restricted to mucosae only, which may be severely affected. Due to the higher level of split within the epidermis, the blisters are flaccid, easily ruptured and often not seen intact. Erosions are common and the Nikolsky sign is positive. The trunk is usually affected. The condition is associated with significant morbidity and mortality.

Investigations

The diagnosis can be made by skin biopsy, which shows intra-epidermal blistering and acantholysis, with positive direct immunofluorescence for IgG (usually IgG1 or IgG4) and C_3 at the periphery of keratinocytes, giving a 'chicken wire' appearance within the epidermis. The titres of circulating epidermal autoantibodies can also be used to monitor disease activity. Investigations should screen for associated autoimmune disease or malignancy if paraneoplastic pemphigus is suspected.

Management

Pemphigus is more difficult to treat than BP and high-dose systemic glucocorticoids such as prednisolone (0.5–1.0 mg/kg/day) are usually required. Azathioprine and cyclophosphamide are most often used as glucocorticoid-sparing agents but a range of other immunosuppressants may be considered for severe recalcitrant disease, including methotrexate, ciclosporin, mycophenolate mofetil, intravenous immunoglobulins, plasma exchange, extracorporeal photopheresis and rituximab. Often, long-term treatment is required to prevent relapse.

26.28 Clinical and investigation findings in the immunobullous disorders

Disease	Site of blisters	Nature of blisters	Mucous membrane involvement	Antigen	Circulating antibody (indirect IF)	Fixed antibody (direct IF)
Pemphigus vulgaris	Trunk, head	Flaccid, fragile, many erosions	100%	Desmoglein-1 and 3 (120 kD)	IgG	IgG, C_3 intercellular (epidermal)
Pemphigus foliaceus	Trunk	Often not present, multiple erosions, may mimic dermatitis	No	Desmoglein-1	IgG	IgG, C_3 intercellular (epidermal)
Bullous pemphigoid	Trunk, flexures and limbs	Tense, milia as blisters resolve	Occasional	BP-230 and 180	IgG (70%)	IgG, C_3 at BMZ
Dermatitis herpetiformis	Elbows, lower back, buttocks	Excoriated and often not present	No	Unknown	Anti-endomysial and tissue transglutaminase	Granular IgA in papillary dermis
Linear IgA disease	Widespread	Tense, often annular configuration, 'string of beads'	Frequent	Unknown	50% have low titres of circulating antibody	Linear IgA at BMZ
Pemphigoid gestationis	Periumbilical and limbs	Tense, milia as blisters resolve	Rare	Collagen XVII (part of hemi-desmosome, BP-180)	Circulating antibodies to BP-180 (type XVII collagen) (and BP-230)	C_3 at BMZ
Epidermolysis bullosa acquisita	Widespread	Tense, scarring, milia	Common (50%)	Type VII collagen	IgG (anti-type VII collagen)	IgG at BMZ
Bullous lupus erythematosus	Widespread	Tense	Rare	Type VII collagen	Anti-type VII collagen	IgG, IgA, IgM at BMZ

(BMZ = basement membrane zone; IF = immunofluorescence; Ig = immunoglobulin)

Andrews' diseases of the skin. 13th ed. Elsevier; 2020.*

Dermatitis herpetiformis

Dermatitis herpetiformis (DH) is an autoimmune blistering disorder that is strongly associated with coeliac disease (CD). While fewer than 10% of individuals with CD develop DH, almost all patients with DH have evidence of partial villous atrophy on intestinal biopsy, even if they have no gastrointestinal symptoms. It is unclear why some CD patients develop DH and others do not. Although DH is a bullous disease, intact vesicles and blisters are seldom seen, as the condition is so pruritic that excoriations on extensor surfaces of arms, knees, buttocks, shoulders and scalp may be the only signs.

The diagnosis can be made by skin biopsy, which shows subepidermal vesiculation in the dermal papillae and a neutrophil- and eosinophil-rich infiltrate. Direct immunofluorescence shows granular IgA in the papillary dermis. Anti-endomysial antibodies and tissue transglutaminase should be assessed and jejunal biopsy undertaken if indicated. The condition usually responds to a gluten-free diet but, if not, dapsone can also be used.

Linear IgA disease

This occurs in children (chronic bullous disease of childhood) and adults, and is usually self-limiting, although it can be active for a few years. Drugs, notably vancomycin, can be a secondary cause. Blisters can arise on erythematous, urticated or otherwise normal-looking skin and often form an annular configuration at the edge of the lesion: 'clusters of jewels' (herpetiform) and 'string of beads' (annular/polycyclic). Mucosal involvement is common, and ophthalmology input is important, as corneal scarring is a risk with longstanding disease. Linear IgA is seen at the basement membrane on direct immunofluorescence and localises to either roof or floor of salt-split skin. Dapsone, sulfapyridine, prednisolone, colchicine or intravenous immunoglobulin may be effective.

Epidermolysis bullosa acquisita

This chronic blistering disease affects skin and mucosae, and scarring, hair loss and nail dystrophy may be problematic. Blisters often follow trauma and milia develop. It can be very difficult to distinguish from other immunobullous diseases, such as bullous pemphigoid. It is caused by an IgG antibody to type VII collagen, which provokes subepidermal blistering and a mixed inflammatory infiltrate, although the latter may not be prominent. Direct immunofluorescence on perilesional skin shows IgG and C_3 at the dermo-epidermal junction and pattern analysis may be helpful in distinction from bullous pemphigoid. Indirect immunofluorescence microscopy on salt-split normal human skin typically shows IgG and IgA in the floor of the artificially induced blister, whereas in BP antibody localisation would be to the roof of the blister. Epidermolysis bullosa acquisita is challenging to treat, as it often does not respond well to immunosuppressants. Mainstays of treatment include systemic glucocorticoids in combination with dapsone or colchicine. Other immunosuppressive approaches may be required and include ciclosporin, azathioprine, immunoglobulins, plasmapheresis and rituximab. The condition may be associated with inflammatory bowel disease, rheumatoid arthritis, multiple myeloma and lymphoma, and thus associated comorbidities should be sought.

Porphyria cutanea tarda and pseudoporphyria

These conditions may also cause blistering (see Boxes 26.5 and 26.9). Porphyria is discussed in more detail in Chapter 19.

Pigmentation disorders

Decreased pigmentation

Disorders causing hypopigmentation and/or depigmentation include:

- vitiligo
- albinism
- pityriasis alba: depigmented areas on the face, particularly in children, with or without scale and usually considered to be eczematous
- pityriasis versicolor: hypopigmentation or, less commonly, hyperpigmentation can occur
- idiopathic guttate hypomelanosis: multiple small areas of depigmentation arising in chronically sun-exposed skin
- rarely, phenylketonuria and hypopituitarism.

Vitiligo

Vitiligo is an acquired condition affecting 1% of the population worldwide. Focal loss of melanocytes results in the development of patches of hypopigmentation. A positive family history of vitiligo is relatively common in those with extensive disease, and this type is also associated with other autoimmune diseases. Trauma and sunburn may (through the Köbner phenomenon) precipitate the appearance of vitiligo. It is thought to be the result of cell-mediated autoimmune destruction of melanocytes but why some areas are targeted and others are spared is unclear.

Clinical features

Generalised vitiligo is often symmetrical and involves hands, wrists, feet, knees (Fig. 26.43) and neck, as well as areas around body orifices. The hair of the scalp, beard, eyebrows and lashes may also depigment. Segmental vitiligo is restricted to one part of the body but not necessarily a dermatome. The patches of depigmentation are sharply defined, and in light-skinned individuals may be surrounded by hyperpigmentation. Spotty perifollicular pigment may be seen within the depigmentation and is often the first sign of repigmentation. There is no history or evidence of inflammation within the patches, which may be helpful in distinguishing

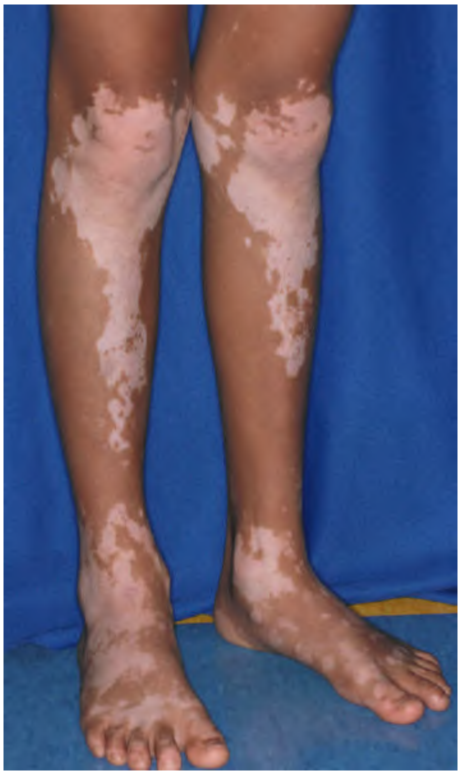

Fig. 26.43 **Vitiligo.** Symmetrical depigmentation of the knees and lower extremities. The dorsal aspect of the feet and hands are particularly hard to repigment. *From Mancini AJ, Paller AS. Hurwitz clinical pediatric dermatology. 5th ed. Elsevier; 2016.*

vitiligo from post-inflammatory hypopigmentation. Sensation in the depigmented patches is normal, unlike tuberculoid leprosy. Wood's light examination enhances the contrast between pigmented and non-pigmented skin. The course is unpredictable; most patches remain static or enlarge but a few undergo repigmentation spontaneously.

Management

Protecting the patches from excessive sun exposure with clothing or sunscreen may be helpful to avoid sunburn. Camouflage cosmetics may be beneficial, particularly in those with dark skin. In fair skin, photoprotection and cosmetic cover may be all that is required. Very potent or potent topical glucocorticoids have limited efficacy with respect to repigmentation. Topical pimecrolimus or tacrolimus may also have a role as a glucocorticoid-sparing agent. Phototherapy with narrowband UVB or PUVA can also be used. Narrowband UVB is the most effective repigmentary treatment available for generalised vitiligo, but even very prolonged courses often do not produce a satisfactory outcome. NICE approval of the topical JAK inhibitor, ruxolitinib and promising clinical trials of oral JAK inhibitors, notably upadacitinib and povorcitinib, provide further therapeutic options for patients with this challenging condition.

The absence of leucotrichia (white hairs in the lesional vitiligo skin) and the presence of a trichrome pattern (three colours – normal skin colour, hypopigmentation and depigmentation) are good prognostic features. Vitiligo on the face, trunk and proximal limbs is more likely to respond than that on hands and feet. Exceptionally, depigmentation of normal non-lesional skin or a surgical approach with autologous melanocyte transfer, using a range of techniques including split-skin grafts and blister roof grafts, is sometimes used on dermabraded recipient skin in specific severe cases.

The impact of vitiligo differs markedly between populations. In South Asia the effects are more readily discernible than in light-skinned individuals in northern Europe. Depigmentation is also seen in leprosy, which means that individuals with vitiligo are often stigmatised. The emotional impact of vitiligo may be immense; psychological support is essential and is important in conveying realistic expectations of possible treatment approaches.

Oculocutaneous albinism

Albinism results from a range of genetic abnormalities that lead to reduced melanin biosynthesis in the skin and eyes; the number of melanocytes is normal (in contrast to vitiligo). Albinism is usually inherited as an autosomal recessive trait and there are several different types and presentations.

Type 1 albinism is due to a defect in the tyrosinase gene, whose product is rate-limiting in the production of melanin. Affected individuals have an almost complete absence of pigment in the skin and hair at birth, with consequent pale skin and white hair, and failure of melanin production in the iris and retina. Patients have photophobia, poor vision not correctable with refraction, rotatory nystagmus, and an alternating strabismus associated with abnormalities in the decussation of nerve fibres in the optic tract.

A second form of albinism is due to a defect in the *P* gene, which encodes an ion channel protein in the melanosome. Patients may have gross reduction of melanin in the skin and in the eyes but may be more mildly affected than type 1 albinos. Establishing the subtype of albinism requires genetic analysis, as there is considerable phenotypic heterogeneity.

Oculocutaneous albinos are at grossly increased risk of sunburn and skin cancer. In equatorial regions, many die from squamous cell carcinoma or, more rarely, melanoma in early adult life. Interestingly, they may develop pigmented melanocytic naevi and freckles in response to sun exposure. Albinism is also highly stigmatised in African countries, such as Tanzania, where the condition is associated with witchcraft and sufferers may be subjected to brutal attacks.

Management

Strict photoprotection, with sun avoidance (including occupational exposure), clothing, hats and sunscreens, is important. Early diagnosis and treatment of skin tumours is essential.

Increased pigmentation

- *Diffuse hyperpigmentation*: most commonly due to hypermelanosis but other pigments may be deposited in the skin, such as orange discoloration with carotenaemia and bronze with haemochromatosis.
- *Endocrine pigmentation*: may occur in several conditions. Melasma (chloasma) describes discrete patches of facial pigmentation that occur in pregnancy and in some women taking oral contraceptives. The mechanism for this localised increased hormonal sensitivity is unknown. Diffuse pigmentation, sometimes worse in the skin creases and mucosae, may be a feature of Addison disease, Cushing syndrome, Nelson syndrome and chronic renal failure due to increased levels of pituitary melanotrophic peptides, including adrenocorticotrophic hormone (ACTH).
- *Photo-exposed site hyperpigmentation*: occurs in some of the porphyrias but can also be drug-induced with amiodarone and chlorpromazine.
- *Drug-induced pigmentation* (Box 26.29): may be diffuse or localised. It is not always due to hypermelanosis but sometimes is caused by deposition of the drug or a metabolite.
- *Focal hypermelanosis*: seen in lesions such as freckles and lentigines, characterised by focal areas of increased pigmentation.

Establishing the cause is important. Photoprotection may minimise the risk of increasing pigmentation. Topical hydroquinone preparations can be used for skin lightening in some types of hyperpigmentation, although caution is required, particularly in darker skin types.

Hair disorders

These can be subdivided into disorders that cause loss of hair (alopecia) or excessive hair growth (hypertrichosis and hirsutism).

26.29 Drug-induced pigmentation

Drug	Appearance
Amiodarone	Photo-exposed sites, slate-grey
Arsenic	Diffuse bronze pigmentation Raindrop depigmentation
Bleomycin	Usually flexural, brown
Busulfan	Diffuse brown
Chloroquine	Photo-exposed sites, blue-grey
Clofazimine	Red
Mepacrine	Yellow
Minocycline	Temples, shins, gingiva, sclera, scar sites, slate-grey
Phenothiazines	Photo-exposed sites, slate-grey
Psoralens	Photo-exposed sites, brown

26.30 Classification and causes of alopecia

Localised	Diffuse
Non-scarring	
Tinea capitis Alopecia areata Androgenetic alopecia Traumatic (trichotillomania, traction, cosmetic) Syphilis	Androgenetic alopecia Telogen effluvium Hypothyroidism Hyperthyroidism Hypopituitarism Diabetes mellitus HIV disease Nutritional (especially iron) deficiency Liver disease Post-partum Alopecia areata Syphilis Drug-induced: chemotherapy, retinoids
Scarring	
Discoid lupus erythematosus Lichen planopilaris Herpes zoster Pseudopelade Tinea capitis/kerion Morphoea (en coup de sabre) Idiopathic Developmental defects	Systemic lupus erythematosus Radiotherapy Folliculitis decalvans Lichen planopilaris

Alopecia

Alopecia is characterised by loss of hair. It can be further subdivided into localised and diffuse, and into scarring and non-scarring subtypes (Box 26.30).

Pathogenesis

Alopecia can be observed in association with inflammatory disorders that cause scarring (lichen planus, discoid lupus) and others that do not cause scarring (tinea capitis, psoriasis, seborrhoeic eczema). These conditions are discussed elsewhere. Alopecia areata has an autoimmune basis and there is a strong genetic component, with a family history in approximately 20% of cases. In addition to atopy, it is associated with other autoimmune diseases, particularly thyroid disease, and with Down syndrome. The cause of androgenetic alopecia is unclear but likely to be multifactorial, with genetic, hormonal and end-organ receptor sensitivity to the factors implicated. Developments in therapeutic approaches with JAK inhibitors provide insights into disease pathogenesis and the pathways involved.

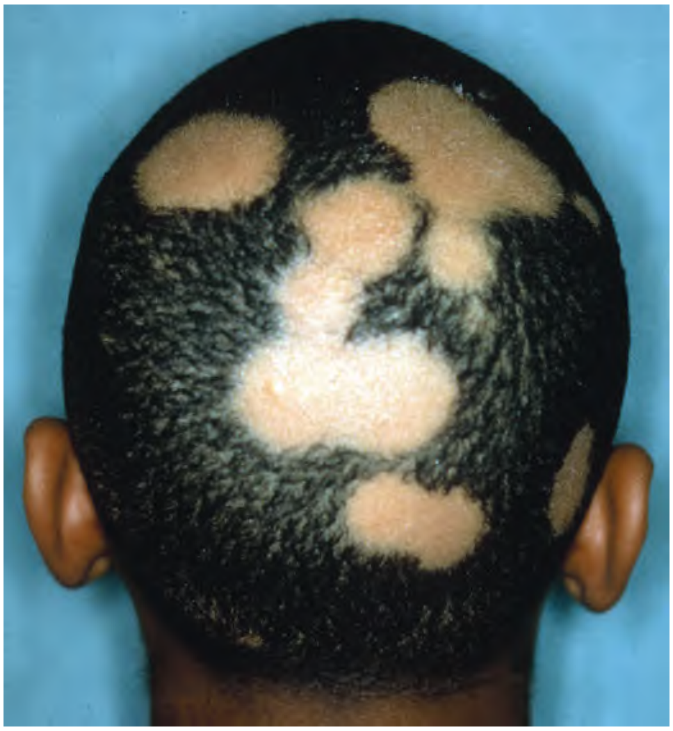

Fig. 26.44 Alopecia areata.

Clinical features

Alopecia areata

This usually presents with well-defined, localised, non-inflammatory, non-scarring patches of alopecia, usually on the scalp (Fig. 26.44). Pathognomonic 'exclamation mark' hairs are seen (broken hairs, tapering towards the scalp) during active hair loss. A diffuse pattern can uncommonly occur on the scalp. Eyebrows, eyelashes, beard and body hair can be affected. Alopecia totalis describes complete loss of scalp hair, and alopecia universalis is complete loss of all hair. Nail pitting may occur. Spontaneous regrowth is usual for small patches of alopecia, but the prognosis is less good for larger patches, more extensive involvement, early onset and an association with atopy.

Androgenetic alopecia

Male-pattern baldness is physiological in men over 20 years old, although it can also occur in adolescents. It is also found in women, particularly after the menopause. Characteristically, this involves bitemporal recession initially and subsequent involvement of the crown ('male pattern'), although it is often diffuse in women.

Investigations

Important investigations include full blood count, renal and liver function tests, iron studies, thyroid function, autoantibody screen and syphilis serology, as several systemic diseases, particularly iron deficiency and hypothyroidism, can cause diffuse non-scarring alopecia. Hair pull tests may help to establish the ratio of anagen to telogen hairs but require expertise for interpretation. Scrapings and plucked hairs should be sent for mycology if there is localised inflammation. Scalp biopsy and direct immunofluorescence of scarring alopecia may confirm a diagnosis of lichen planus or discoid lupus erythematosus, but expert interpretation is needed.

Management

Any underlying condition, such as iron deficiency, should be treated and may result in clinical improvement. Alopecia can have a major impact on quality of life and psychological support is usually required. It is particularly important to establish realistic expectations.

Hair may spontaneously regrow in alopecia areata, and it may be appropriate to offer no active intervention as, while some treatments may induce some hair regrowth, there is no evidence that any treatment fundamentally alters the course of the disease. There may be some response to topical or intralesional glucocorticoids. PUVA or immunotherapy with diphencyprone may be effective, with evidence of hair regrowth, but there is a risk of relapse on discontinuation of treatment. Short courses of systemic glucocorticoids are occasionally used to try to limit acutely progressive extensive alopecia areata but should not be used long term; the risk of relapse on discontinuation is high. Clinical trials of JAK inhibitors, with ritlecitinib and baricitinib becoming available for use, offer hope to patients with severe alopecia areata. Some males with androgenetic alopecia may be helped by systemic finasteride. Topical minoxidil can be used in males and females with androgenetic alopecia but, if an effect is obtained, treatment must be continued and is expensive. In females, anti-androgen therapy, such as cyproterone acetate, can be used. Wigs are often appropriate for extensive alopecia. Scalp surgery and autologous hair transplants are expensive but can be used for androgenetic alopecia.

Hypertrichosis

Hypertrichosis is a generalised or localised increase in hair and may be congenital or acquired. It can be primary or secondary: for example, to drugs such as ciclosporin, minoxidil or diazoxide, malignancy or eating disorders. Laser therapy or eflornithine, which inhibits ornithine decarboxylase and arrests hair growth while it is used, may be helpful. When the hypertrichosis follows a male pattern, it is called hirsutism.

Hirsutism

Hirsutism is the growth of terminal hair in a male pattern in a female. The cause of most cases is unknown and, while it may occur in hyperandrogenism, Cushing syndrome and polycystic ovary syndrome, only a small minority of patients have a demonstrable hormonal abnormality. Psychological distress is often significant and oral contraceptives containing an anti-androgen such as cyproterone acetate, laser therapy or topical eflornithine may be beneficial.

Nail disorders

The nails can be affected by both local and systemic disease. The nail apparatus consists of the nail matrix and the nail plate, which arises from the matrix and lies on the nail bed (Fig. 26.45). The cells of the matrix and, to a lesser extent, the bed produce the keratinous plate.

Important information may be obtained from nail-fold examination, including dilated capillaries and ragged cuticles in connective tissue disease (Fig. 26.46) and the oedematous inflammation of paronychia. The latter commonly occurs chronically in individuals undertaking wet work, in those with diabetes or poor peripheral circulation, and following cosmetic nail procedures and vigorous manicuring.

Normal variants

Longitudinal ridging and beading of the nail plate occur with age. White transverse patches (striate leuconychia) are often caused by airspaces within the plate.

Nail trauma

- *Nail biting/picking* is a very common habit. Repetitive proximal nail-fold trauma (often involving the thumb nail) results in transverse ridging and central furrowing of the nail.
- *Chronic trauma* from poorly fitting shoes and sport can cause thickening and disordered growth of the nail (onychogryphosis) and subsequent ingrowing toenails.
- *Splinter haemorrhages* are fine, linear, dark brown longitudinal streaks in the plate (see Fig. 16.86). They are usually caused by trauma, especially if distal. Uncommonly, they can occur in nail psoriasis and are also a hallmark of infective endocarditis.

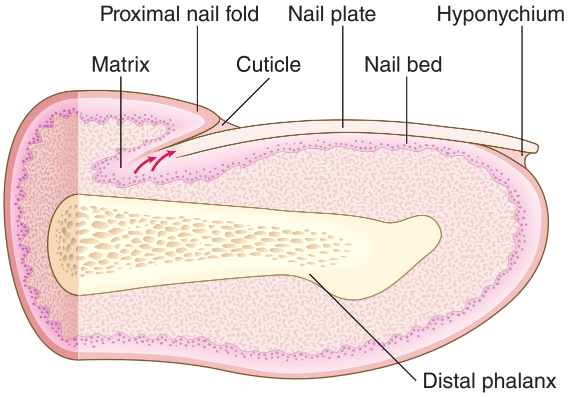

Fig. 26.45 **The nail plate and bed.** Arrows indicate the direction of nail growth.

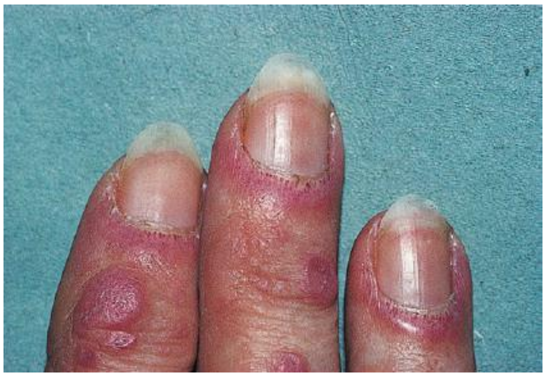

Fig. 26.46 **Dermatomyositis.** Note the prominent periungual involvement. Erythema, dilated and tortuous capillaries in the proximal nail fold, and ragged cuticles are features of connective tissue disease.

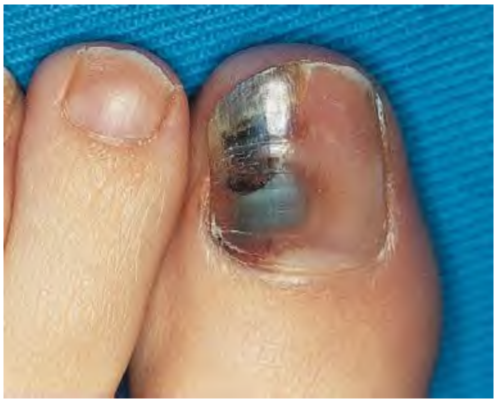

Fig. 26.47 **Subungual haematoma.**

- *Subungual haematoma* is red, purple or grey–brown discoloration of the nail plate, usually of the big toe (Fig. 26.47). These haematomas are usually due to trauma, although a history of this may not be clear. The main differential is subungual melanoma, although rapid onset, lack of nail-fold involvement and proximal clearing as the nail grows are clues to the diagnosis of haematoma. If there is diagnostic doubt, a biopsy may be needed.

Nail involvement in skin diseases

- *Dermatophyte infection/onychomycosis*: features are described earlier in the chapter in the section on skin infection.
- *Psoriasis*: nail involvement is common (see Fig. 26.36B).

- *Eczema*: nails may be shiny due to rubbing skin. Fine pitting can occur. If there is periungual eczema, the nail may become dystrophic, with thickening and transverse ridging. Paronychia is common.
- *Lichen planus*: there may be longitudinal ridging and thinning of the nail, giving a sandpaper texture (trachyonychia), erythematous streaks (erythronychia), subungual hyperkeratosis, pigmentation and, in severe cases, pterygium (splitting of nail due to central fibrosis and scarring, giving a winged appearance) and a destructive nail dystrophy.
- *Alopecia areata*: nail-plate pitting and trachyonychia can occur.

Nail involvement in systemic disease

The nails may be affected in many systemic diseases and important examples are detailed below:

- *Beau lines*: horizontal ridges/indentations in the nail plate occur simultaneously in all nails (Fig. 26.48B). They typically follow a systemic illness and are thought to be due to temporary growth arrest of cells in the nail matrix; they subsequently migrate out as the nail grows. Normal nail growth is approximately 0.1 mm/day for fingers and 0.05 mm/day for toes, so the timing of the systemic upset can usually be estimated by the position of the Beau lines.
- *Koilonychia*: this concave or spoon-shaped nail-plate deformity is caused by iron deficiency (Fig. 26.48C).
- *Clubbing*: in the early stages, the angle between the proximal nail and nail fold is lost. In its more established form, there may be swelling of the distal digits (Figs. 26.48D and E) or toes. Causes include bronchogenic carcinoma, asbestosis (especially with mesothelioma), suppurative or fibrosing lung disease, cyanotic congenital heart disease, infective endocarditis, inflammatory bowel disease, biliary cirrhosis and thyrotoxicosis; rarely, clubbing can be familial or idiopathic.
- *Nail discoloration*: whitening may occur in hypoalbuminaemia. 'Half-and-half' nails (white proximally and red/brown distally) may be found in renal failure. Antimalarials and some other drugs occasionally discolour nails.

Nail involvement in congenital disease

Nails can be affected in congenital diseases, such as pachyonychia congenita, a rare, usually autosomal dominant condition caused by mutations in differentiation-specific keratin genes 6A, 6B, 16 and 17. This results in palmoplantar keratoderma and gross nail discoloration and thickening, due to subungual hyperkeratosis, from birth.

Skin disease in general medicine

Many skin conditions present to other medical specialties. These are listed in Box 26.31 and the most common ones that are not discussed elsewhere are detailed below.

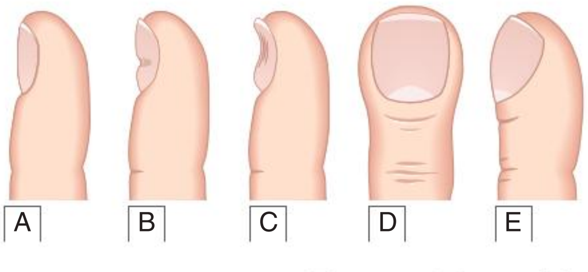

Fig. 26.48 The nail in systemic disease. **A** Normal nail. **B** Beau line. **C** Koilonychia. **D** and **E** Digital clubbing.

Conditions involving cutaneous vasculature

Vasculitis

Vasculitic involvement of the skin usually presents as palpable purpura (see Fig. 25.51B). The diagnosis is confirmed by skin biopsy, along with histology and immunofluorescence examination. Vasculitis is discussed in more detail in Chapter 25.

Pyoderma gangrenosum

The initial lesion of pyoderma gangrenosum (PG) is usually a painful, tender, inflamed nodule or pustule, which breaks down centrally and rapidly progresses to an ulcer with an indurated, undermined purplish or pustular edge (Fig. 26.49). Lesions may be single or multiple and are classified as ulcerative, pustular, bullous or vegetative. PG usually occurs in adults and, although it may occur in isolation, is usually associated with underlying disease, particularly inflammatory bowel disease, inflammatory arthritis, blood dyscrasias, immunodeficiencies and HIV infection. Investigation should be made with these associations in mind. The diagnosis is largely clinical, as histology is not specific. Analgesia, treatment of secondary bacterial infection and supportive dressings are important. Systemic treatment with glucocorticoids, dapsone, ciclosporin or other immunosuppressants is often required. Prednisolone and ciclosporin were shown to be of similar efficacy in a randomised controlled trial and can both be considered for pyoderma gangrenosum, allowing individual patient comorbidities and risk factors to be taken into account. Tetracyclines may be added for their anti-inflammatory effects. There are reports of efficacy with TNF-α (infliximab, adalimumab), IL-12/23 (ustekinumab) and IL-17 (brodalumab and secukinumab) inhibitors for severe recalcitrant PG, although as this is a rare orphan

i 26.31 Skin problems in general medicine

Primary skin problems

- Cellulitis
- Vasculitis
- Leg ulcers
- Pressure sores

Skin involvement in multisystem disease

- Genetic: neurofibromatosis, tuberous sclerosis
- Xanthomas
- Amyloidosis
- Porphyria
- Sarcoidosis
- Systemic lupus erythematosus
- Systemic sclerosis

Non-specific and variable skin reactions to systemic disease

- Urticaria
- Erythema multiforme
- Annular erythemas
- Erythema nodosum
- Pyoderma gangrenosum
- Sweet syndrome
- Generalised pruritus

Skin conditions associated with malignancy

- Dermatomyositis
- Generalised pruritus
- Acanthosis nigricans
- Superficial thrombophlebitis

Skin problems associated with specific medical disorders

- Liver: generalised pruritus, pigmentation, spider naevi, palmar erythema, nail clubbing
- Kidney: generalised pruritus, uraemic frost, pigmentation
- Diabetes mellitus: necrobiosis lipoidica, diabetic dermopathy
- Cutaneous Crohn disease

Skin problems secondary to treatment of systemic disease

- Drug eruptions

Miscellaneous

- Granuloma annulare
- Morphoea

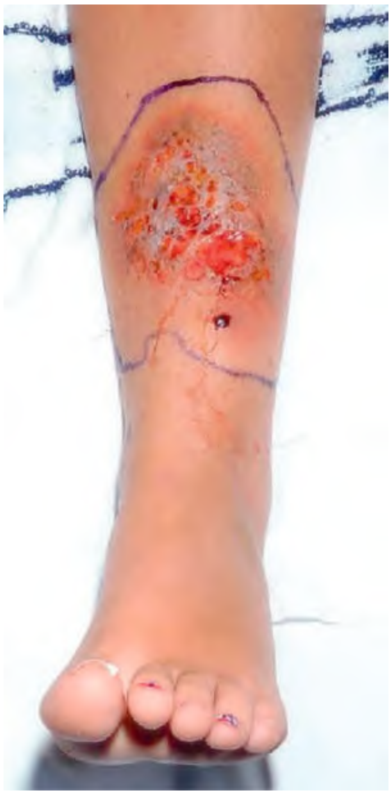

Fig. 26.49 **Pyoderma gangrenosum.** This young patient had Crohn disease. Note the cribriform pattern of re-epithelialisation, which is characteristic of this condition.

disease, evidence is relatively limited. Once healing has taken place, recurrences are typically only intermittent.

Other neutrophilic dermatoses

These include Sweet acute febrile neutrophilic dermatosis and the neutrophilic dermatosis of rheumatoid disease, which are characterised by intense inflammation, mainly consisting of neutrophils, around dermal blood vessels. There can be damage to vessels ('vasculopathy') but usually no frank vasculitis.

Pressure sores

Localised, prolonged, pressure-induced ischaemia can lead to the development of pressure sores, which can occur in up to 30% of hospitalised older adults. They are associated with considerable morbidity, mortality and expense to health services. The main risk factors are immobility, poor nutrition, local tissue hypoxia – for example, with anaemia, peripheral vascular disease, diabetes, sepsis and skin atrophy – or barrier impairment, such as in eczema.

A localised area of erythema develops at sites of bony prominences (particularly sacrum, greater trochanter, ischial and calcaneal tuberosities, and lateral malleolus). This progresses to a blister and then erosion, which will develop into a deep necrotic ulcer, usually colonised by *Pseudomonas aeruginosa* if pressure is not alleviated.

Prevention is key and involves identification of at-risk patients and regular repositioning and use of pressure-relieving mattresses. Predisposing factors, such as anaemia and poor nutrition, should be corrected. Once established, significant infection must be treated and necrotic tissue debrided. Dressings encourage granulation, although surgical intervention may sometimes be needed.

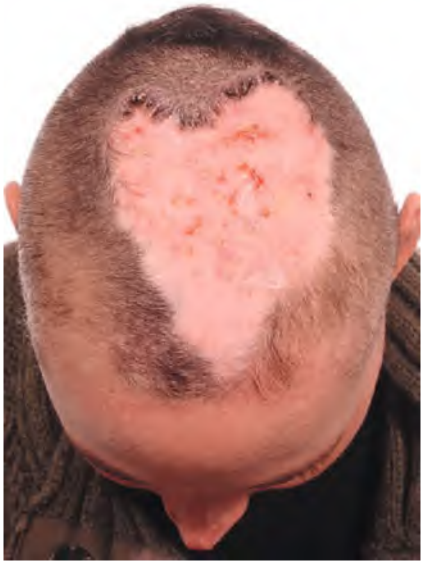

Fig. 26.50 **Scarring inflammatory alopecia.** This patient had systemic lupus erythematosus and additional cutaneous features of scarring inflammatory discoid lupus erythematosus.

Connective tissue disease

Lupus erythematosus

This autoimmune disorder can be subdivided into systemic lupus erythematosus (SLE) and cutaneous lupus, which includes discoid lupus erythematosus (DLE) and subacute cutaneous lupus erythematosus (SCLE). The features of SLE are discussed in Chapter 25 (see Box 25.62, and Boxes 26.34 and 26.35 below). DLE typically presents as scaly red plaques with follicular plugging, usually on photo-exposed sites of the face, head and neck, which resolve with scarring and pigmentary change. If the scalp is involved, scarring alopecia usually occurs (Fig. 26.50). Most patients with DLE do not develop SLE. Patients with SCLE may have extensive cutaneous involvement, usually aggravated by sun exposure, with an annular, polycyclic or papulosquamous eruption. SCLE is often drug-triggered, systemic involvement is uncommon and the prognosis usually good. There is a strong association with antibodies to Ro/SS-A antigen. A diagnosis of cutaneous lupus is confirmed by histopathology and direct immunofluorescence. Cutaneous lupus may respond to topical glucocorticoids, antimalarials or immunosuppressants, with advances in biologics such as belimumab and anifrolumab (covered in Chapter 25). Antimalarials and photoprotection are important mainstays in the management of cutaneous lupus, and systemic immunosuppression may be required for resistant disease. Paradoxically, low-dose UVA1 phototherapy can be effective for lupus.

Systemic sclerosis

This autoimmune multisystem disease presents with severe Raynaud syndrome, digital ulcers and skin fibrosis. Dilated nail-fold capillaries and ragged cuticles are frequent. The clinical features and management are described in Chapter 25.

Morphoea

Morphoea is a localised cutaneous form of scleroderma that can affect any site at any age. It usually presents as a thickened violaceous plaque, which may become hyper- or hypopigmented. Plaques can become generalised. Linear forms exist and, if in the scalp, are associated with scarring hair loss (en coup de sabre). There is usually no systemic involvement. Topical glucocorticoids or immunosuppressants or phototherapy, particularly PUVA or UVA1, can be effective, and systemic immunosuppression may be used for resistant extensive disease.

Dermatomyositis

Dermatomyositis is a multisystem disease, predominantly affecting skin, muscles and blood vessels. Typical cutaneous features include a violaceous 'heliotrope' erythema periorbitally, and involving the upper eyelids, but this can sometimes affect the upper trunk, shoulders ('shawl sign') and limbs. Linear erythematous streaks may also be observed on the back of hands and fingers, and papules over the knuckles (Gottron papules). Tortuous dilated nail-fold capillaries, often best seen with a dermatoscope, and ragged cuticles are usually evident (see Fig. 26.46). Photo-aggravation of the cutaneous features is often prominent (Fig. 26.51). The clinical features and management are described in Chapter 25.

Granulomatous disease

Granuloma annulare

This is common and may be reactive, although a trigger is usually not apparent. The hallmark is the presence of dermal granulomas, which are usually palisading and associated with alteration of dermal collagen (necrobiosis). The condition is generally asymptomatic and may present as an isolated dermal lesion with a raised papular annular edge or may be more generalised. An association between generalised disease and diabetes has been proposed but not confirmed. Lesions often resolve spontaneously. Intralesional glucocorticoids or cryotherapy can be used for localised disease, and UVB or UVA1 phototherapy or PUVA for generalised disease.

Necrobiosis lipoidica

This condition has some histological features in common with granuloma annulare, although necrobiosis predominates. The lesion has a characteristic yellow, waxy, atrophic appearance, often with a violaceous edge (Fig. 26.52). Underlying blood vessels are easily seen because of tissue atrophy. Necrobiosis lipoidica typically appears on the shins and is prone to ulceration after trauma. There is a strong association with diabetes: most patients with necrobiosis lipoidica have or develop diabetes, although less than 1% of diabetic patients develop necrobiosis lipoidica. Treatment is difficult and includes very potent topical or intralesional glucocorticoids, topical calcineurin inhibitors, PUVA or UVA1 phototherapy, PDT and systemic immunosuppression.

Sarcoidosis

This condition is characterised by the presence of non-caseating granulomas. The cause is unknown, although infectious and genetic factors have been proposed. It is usually a multisystem disease, with skin lesions in about one-third of patients. Cutaneous features can occur in isolation and include violaceous infiltrated dermal plaques and nodules, which can affect any site but particularly digits and nose (lupus pernio), more generalised hyper- or hypopigmented or annular papules and plaques, infiltrative changes in scars and erythema nodosum (see Fig. 17.58). It has been reported more commonly and may be more severe in those of African, African American or South Asian ancestry. Cutaneous disease may respond to topical or intralesional glucocorticoids, cryotherapy, UVA1, laser or PDT. Clinical features, investigation and management of systemic disease are discussed in Chapter 17.

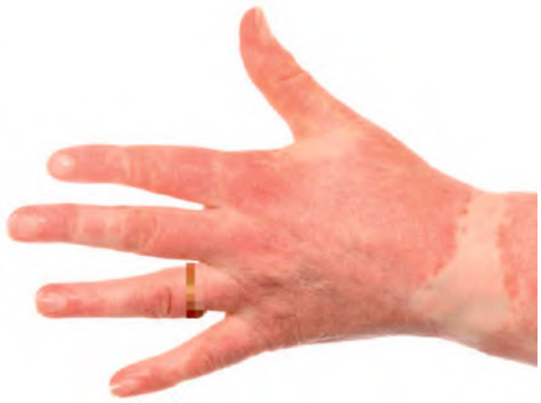

Fig. 26.51 Dermatomyositis. Photo-aggravation in dermatomyositis.

Cutaneous Crohn disease

Cutaneous Crohn disease is rare but may present as perianal and peristomal infiltrative plaques, lymphoedema, sinuses or fistulae, and oral granulomatous disease. These changes are termed 'metastatic' Crohn disease and histology shows non-caseating granulomas. Reactive skin changes can also occur in the form of erythema nodosum and pyoderma gangrenosum. Treatment is of the underlying disease.

Porphyrias

The porphyrias are a diverse group of diseases, caused by reduced or absent activity of specific enzymes in the porphyrin–haem biosynthetic pathway. Due to this loss of enzyme activity, porphyrin precursors proximal to the implicated enzyme step accumulate. If the accumulated porphyrins absorb visible light, then there will be skin features and photosensitivity, which explains why some porphyrias have skin features (porphyria cutanea tarda) and others do not (acute intermittent porphyria). The most common skin presentations are photo-exposed site blistering, skin fragility and pain on daylight exposure.

Cutaneous porphyrias: fragility and blisters

Although porphyria cutanea tarda (PCT) may be genetically inherited, this is uncommon and acquired PCT is the most common porphyria worldwide. It is caused by an underlying chronic liver disease, in association with hepatic iron overload. The liver disease is often only diagnosed through investigation of the skin presentation, and it is thus an important diagnosis not to miss. Typical features are increased skin fragility, blistering, erosions, hypertrichosis, scarring and milia

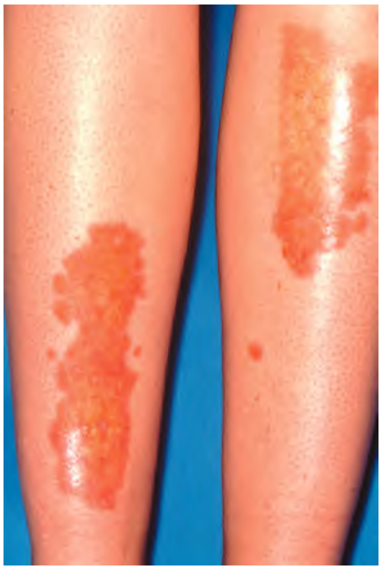

Fig. 26.52 Necrobiosis lipoidica. Atrophic yellow plaques with violaceous edges on the shins of a patient with diabetes mellitus.

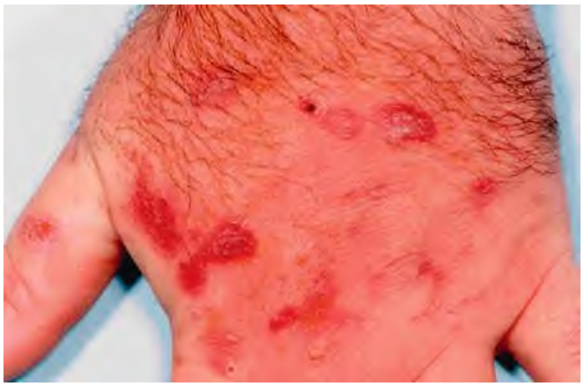

Fig. 26.53 **Porphyria cutanea tarda.** Skin fragility, blistering, scarring, milia and hypertrichosis on the back of hands and fingers in hepatitis C.

occurring on light-exposed areas, particularly the backs of the hands (Fig. 26.53). Less common features include facial hypertrichosis, hyperpigmentation and morphoea-like changes. Variegate porphyria (VP) and hereditary coproporphyria (HCP) may be indistinguishable on skin features and it is important to make the correct diagnosis, as acute neurovisceral attacks, which may be drug-induced, can occur in VP and HCP but not in PCT. Pseudoporphyria may also be impossible to distinguish from PCT on clinical grounds but is most frequently caused by a drug (commonly naproxen; see Box 26.35) or by sunbed use; on investigation, porphyrins are normal. A PCT-like presentation may also be seen in uraemia due to renal failure but is caused by raised porphyrins due to impaired elimination rather than an enzyme defect.

Management of PCT requires removal or treatment of any underlying cause, which may involve venesection, iron chelation, very low-dose hydroxychloroquine once or twice per week and photoprotection.

Cutaneous porphyria: pain on sun exposure

Erythropoietic protoporphyria is caused by a genetic defect in the ferrochelatase gene that leads to ferrochelatase enzyme deficiency. It is an important diagnosis to consider. The presentation is usually in early childhood, although the diagnosis is often delayed. In part this is because, although the baby or child cries due to immediate pain on sunlight exposure, physical signs are often absent or minimal and thus a link with sunlight may not always be considered. The deficient ferrochelatase activity leads to accumulation of lipid-soluble protoporphyrins in the skin, explaining the photosensitivity manifest as pain on daylight exposure. Multiple pigment gallstones, anaemia (usually only problematic if considered to be due to iron deficiency) and, rarely, severe liver disease can occur, which may be fatal and requires liver transplantation. In addition to photoprotection, UVB phototherapy may be effective for the symptoms of photosensitivity and, more recently, the use of alpha-melanocyte-stimulating hormone (α-MSH) analogues as either subcutaneous implant or as being trialed orally, provide further options for patients with this challenging disease.

Abnormal deposition disorders

Xanthomas

Deposits of fatty material in the skin, subcutaneous fat and tendons may be the first clue to primary or secondary hyperlipidaemia.

Amyloidosis

Cutaneous amyloid may present as periocular plaques in primary systemic amyloidosis and amyloid associated with multiple myeloma but is uncommon in systemic amyloidosis secondary to rheumatoid arthritis or other chronic inflammatory diseases. Amyloid infiltration of blood vessels may manifest as 'pinch purpura' following skin trauma. Macular amyloid is more common in darker skin types and appears as pruritic grey/brown macules or patches, usually on the back. Potent topical glucocorticoids can be beneficial, although it is often treatment resistant.

Genetic disorders

Neurofibromatosis

This condition can present with skin lesions. More details are provided in Chapter 27.

Tuberous sclerosis

This is an autosomal dominant condition, and two genetic loci have been identified: *TSC1* (chromosome 9) encoding hamartin, and *TSC2* (chromosome 16) encoding tuberin. The hallmark is hamartomas in many systems. The classic triad of clinical features comprises learning disability, epilepsy and skin lesions but there is marked heterogeneity in clinical features. Skin changes include pale oval (ash leaf) macules that occur in early childhood; yellowish/pink papules in the mid-face (angiofibromas, 'adenoma sebaceum'), occurring in adolescence; periungual and subungual fibromas; and connective tissue naevi (shagreen patches, often on lower back). Gum hyperplasia, retinal phakomas (fibrous overgrowths), renal, lung and heart tumours, cerebral gliomas and calcified basal ganglia may also occur.

Reactive disorders

Erythema multiforme

Erythema multiforme has characteristic clinical and histological features and can be triggered by a variety of factors (Box 26.32), and generally is considered to be predominantly a reactive phenomenon to infection, although a cause is not always identified and underlying systemic or drug causes must also be considered. The disease is likely to have an immunological basis. Lesions are multiple, erythematous, annular, targetoid 'bull's eyes' (Fig. 26.54) and may blister. Extensive disease with mucosal involvement and systemic upset can sometimes occur. Removal/treatment of any trigger is essential. Analgesia and topical glucocorticoids may provide symptomatic relief and supportive care is required and may require urgent ophthalmology referral if there is ocular involvement.

Erythema nodosum

This is characterised histologically by a septal panniculitis of subcutaneous fat (see Fig. 17.58). An identified trigger is often present (Box 26.33). Lesions are typically painful, indurated violaceous nodules on the shins and lower legs. Systemic upset, arthralgias and fever are common. Spontaneous resolution occurs over a month or so, leaving bruise-like marks. Any underlying cause should be identified and removed or treated. Bed rest, leg elevation and an oral NSAID frequently offer symptomatic relief. Systemic glucocorticoids are effective but seldom required and must be avoided when there is a possibility of infection. Potassium iodide, dapsone or hydroxychloroquine may be effective for resistant disease, but are rarely required.

Acquired reactive perforating dermatosis

The hallmark of this condition is transepidermal elimination of dermal material, particularly collagen and elastic tissue. It presents as keratotic papules, particularly in patients with diabetes and chronic renal disease. Treatment with topical glucocorticoids, retinoids, PUVA or UVA1 therapy may help. There are other related perforating dermopathies, with characteristic histology.

Annular erythemas

This group of chronic, poorly defined, annular, erythematous and often scaly eruptions can be further subdivided and may be secondary to an

26.32 Provoking factors in erythema multiforme

Infections

- Viral: herpes simplex, orf, infectious mononucleosis, hepatitis B, HIV
- *Mycoplasma* and other bacterial infections

Drugs

- Sulphonamides, penicillins, barbiturates and carbamazepine

Systemic disease

- Sarcoidosis, malignancy, systemic lupus erythematosus

Other

- Radiotherapy, pregnancy

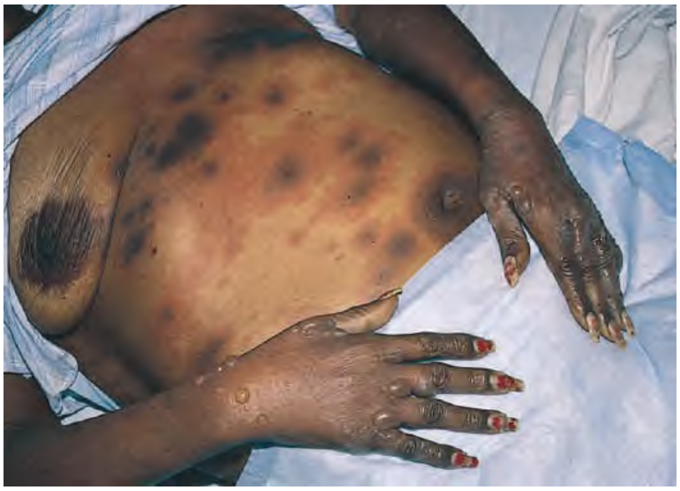

Fig. 26.54 Severe bullous erythema multiforme. *From Swartz MH. Textbook of physical diagnosis. 8th ed. Elsevier; 2021.*

26.33 Provoking factors in erythema nodosum

Infections

- Bacteria: streptococci, mycobacteria, *Brucella*, *Mycoplasma*, *Rickettsia*, *Chlamydia*
- Viruses: hepatitis B and infectious mononucleosis
- Fungi

Drugs

- Sulphonamides, sulphonylureas, oral contraceptives

Systemic disease

- Sarcoidosis, inflammatory bowel disease, malignancy

Other

- Pregnancy

identifiable cause. Erythema chronicum migrans can be associated with Lyme disease *(Borrelia burgdorferi)*. Erythema marginatum can occur in rheumatic fever or Still disease. Erythema gyratum repens typically presents as concentric circles of erythema and scale with an advancing edge and is usually associated with underlying malignancy. Erythema annulare centrifugum presents with expanding, scaly, erythematous rings, with central fading. A trigger may not be apparent but possible associations include fungal infection, drugs, autoimmune or endocrine diseases, such as lupus or thyroid disease, and malignancy, particularly haematological. An underlying trigger must be sought and removed or treated. Topical glucocorticoids or phototherapy may be helpful for chronic disease.

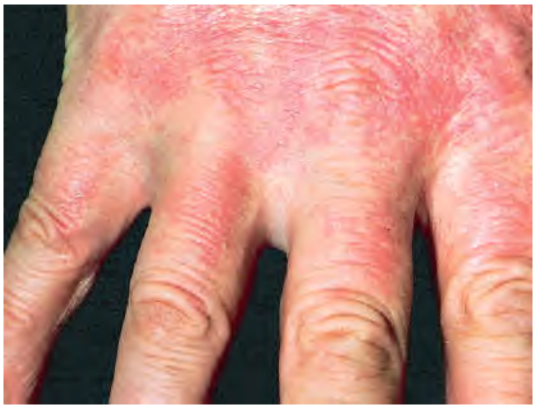

Fig. 26.55 Drug eruption. Possible drug causes of rash should always be considered. This was doxycycline-induced photosensitivity in a farmer.

26.34 Types of drug eruption

Non-immunological

Predictable

- Striae due to glucocorticoids (see Fig. 26.10)
- Asteatosis with statins
- Candidal infections with antibiotics
- Worsening of psoriasis with lithium, β-blockers, antimalarials, NSAIDs
- Urticaria with aspirin due to mast cell degranulation
- Bradykinin-mediated angioedema due to ACE inhibitors
- Doxycycline photosensitivity
- Dapsone haemolysis

Immunological

Unpredictable

- Immediate IgE-mediated hypersensitivity (type I): penicillin-induced urticaria and anaphylaxis
- Antibody-mediated (type II): penicillin-induced haemolysis
- Immune complex-mediated (type III): drug-induced serum sickness or vasculitis
- Delayed hypersensitivity (type IV): drug-induced erythema multiforme, lichenoid or pemphigus-like reaction; drug-induced lupus

(ACE = angiotensin-converting enzyme; IgE = immunoglobulin E; NSAIDs = non-steroidal anti-inflammatory drugs)

Acanthosis nigricans

Hyperkeratosis and pigmentation are typical and affected sites have a velvety texture. The flexures, especially axillae and, in dark-skinned people, sides of neck, are involved. There are several types, mainly associated with insulin resistance. Most often, acanthosis nigricans is found in conjunction with obesity and regresses with weight loss. It can be associated with malignancy, usually adenocarcinoma (particularly gastric), when it is usually more extensive and pruritic, and can involve mucous membranes.

Drug eruptions

Virtually all drugs may have cutaneous adverse effects (Fig. 26.55) and this should be considered in the differential diagnosis of most presentations of skin disease. Drugs can exert their adverse effects via several mechanisms, which can be broadly subdivided into non-immunological and immunological (Box 26.34).

Clinical features

Cutaneous drug reactions typically present in specific patterns (Box 26.35). Non-immunologically mediated reactions can theoretically occur in anyone, given sufficient exposure to the drug, although idiosyncratic factors, such as genetic predisposition, may render some more

26.35 Clinical patterns of drug eruptions

Reaction pattern	Clinical features	Examples of causative drugs
Exanthematous	Erythema, maculopapular	Antibiotics (especially ampicillin), anticonvulsants, gold, penicillamine, NSAIDs, carbimazole, anti-TNF drugs and other biologic therapies
Urticaria and angioedema	Sometimes accompanied by angioedema Angioedema alone	Salicylates, opiates, NSAIDs, antibiotics, dextran, ACE inhibitors
Lichenoid	Violaceous, lichen planus-like, dyspigmentation	Gold, penicillamine, antimalarials, thiazides, NSAIDs, β-blockers, ACE inhibitors, sulphonamides, lithium, sulphonylureas, proton pump inhibitors, quinine, antituberculous drugs, dyes in colour developers
Purpura and vasculitis	Palpable purpura and necrosis	Allopurinol, antibiotics, ACE inhibitors, NSAIDs, aspirin, anticonvulsants, diuretics, oral contraceptives
Erythema multiforme	Target-like lesions and bullae on extensor aspects of limbs	See Box 26.32
Erythema nodosum	Tender, painful, dusky, erythematous nodules on shins	See Box 26.33
Exfoliative dermatitis	There may be erythroderma	Allopurinol, carbamazepine, barbiturates, penicillins, PAS, isoniazid, gold, lithium, penicillamine, ACE inhibitors
Toxic epidermal necrolysis	Rapid evolution, extensive blistering, erythema, necrolysis, mucosal involvement	Anticonvulsants, antibiotics, especially sulphonamides, NSAIDs, terbinafine, sulphonylureas, antiretrovirals, allopurinol
Photosensitivity	Photo-exposed site rash, may be sunburn-like, exfoliation, lichenoid	Thiazides, amiodarone, quinine, NSAIDs, tetracyclines, fluoroquinolones, phenothiazines, sulphonamides, retinoids, psoralens
Drug-induced lupus	Photosensitivity, discoid lesions, urticarial or erythema multiforme-like. May have positive lupus serology and anti-histone antibodies	Allopurinol, thiazides, ACE inhibitors, PAS, anticonvulsants, β-blockers, gold, hydralazine, minocycline, penicillamine, lithium, proton pump inhibitors
Psoriasiform rash	Rash resembles psoriasis	See Box 26.23
DRESS	Facial oedema, fever, extensive rash, lymphadenopathy, eosinophilia and systemic involvement	Anticonvulsants, trimethoprim, minocycline, allopurinol, dapsone, terbinafine
AGEP/toxic pustuloderma	Rapid onset of sterile, non-follicular pustules on erythematous base	Ampicillin/amoxicillin, erythromycin, quinolones, sulphonamides, terbinafine, diltiazem, hydroxychloroquine
Acneiform eruptions	Rash resembles acne	Lithium, anticonvulsants, oral contraceptives, androgens, glucocorticoids, antituberculous drugs, EGFR antagonists (cetuximab and erlotinib)
Pigmentation		See Box 26.29
Bullous eruptions	Often at pressure sites and there may be other features, such as purpura, milia	Barbiturates, penicillamine, furosemide
Pseudoporphyria	May be indistinguishable from porphyria cutanea tarda clinically	NSAIDs, tetracyclines, retinoids, furosemide, nalidixic acid
Exacerbation of acute hepatic porphyrias		See page 1143 Always check all drugs for safety of use in porphyrias against standard guidelines
Drug-induced immunobullous disease	May resemble pemphigoid, pemphigus, dermatomyositis, scleroderma, epidermolysis bullosa acquisita	Penicillamine, ACE inhibitors, vancomycin
Fixed drug eruptions	Round/oval, erythema, oedema ± bullae Same site every time drug is given Pigmentation on resolution	Tetracyclines, sulphonamides, penicillins, quinine, NSAIDs, barbiturates, anticonvulsants
Hair loss	Diffuse	Cytotoxic agents, oral retinoids, anticoagulants, anticonvulsants, antithyroid drugs, lithium, oral contraceptives, infliximab
Hypertrichosis	Excessive hair growth in non-androgenic distribution	Diazoxide, minoxidil, ciclosporin

(ACE = angiotensin-converting enzyme; AGEP = acute generalised exanthematous pustulosis; DRESS = drug rash with eosinophilia and systemic symptoms; EGFR = epidermal growth factor receptor; NSAIDs = non-steroidal anti-inflammatory drugs; PAS = para-aminosalicylic acid; TNF = tumour necrosis factor)

26.36 Diagnostic clues to drug eruptions

- Past history of reaction to suspected drug
- Introduction of suspected drug a few days to weeks before onset of rash
- Recent prescription of a drug commonly associated with rashes (penicillin, sulphonamide, thiazide, allopurinol)
- Symmetrical eruption that fits with a well-recognised pattern, caused by a current drug
- Resolution of rash following drug cessation

susceptible. There is limited information on genetic determinants of drug responses and adverse effects, although advances have been made, providing opportunities for personalised medicine. Immunologically mediated cutaneous drug eruptions typically commence within days to weeks of starting the drug. Detailed history-taking relating to prescribed and non-prescribed medications is essential and there may be other clues (Box 26.36).

Investigations and management

The suspected drug must be stopped. If drug-induced photosensitivity is considered, the patient should be phototested while on the drug to confirm the diagnosis, and again after drug withdrawal to confirm resolution of photosensitivity. An eosinophilia and abnormalities in liver function tests may occur in adverse drug reactions and, for example, specific IgE to penicillin may be raised in penicillin-induced rash but, otherwise, specific investigations are not available. Rechallenge with drug is not usually undertaken unless the reaction is mild, as this can be risky. Drug withdrawal may not be straightforward and substitute drugs may be required. Antihistamines and/or topical or systemic glucocorticoids may provide supportive management, depending on the type of cutaneous reaction. The management of anaphylaxis is described in Chapter 10.

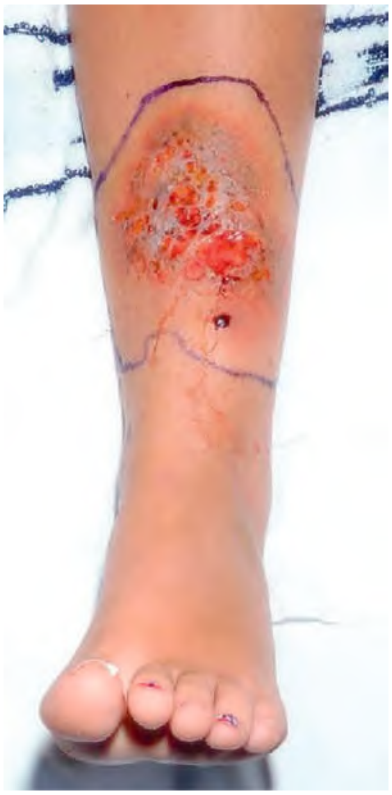
Multiple Choice Questions

26.1. A 29-year-old woman with type 1 diabetes mellitus and Crohn disease presented with an 8-week history of a painful enlarging ulcer on her shin. It had started as a tender lump, which she thought developed after an insect bite. She was otherwise well, with no fever, although reported fatigue and malaise in recent weeks. Examination revealed a large superficial ulcer on the shin, with a raised violaceous edge (see figure). What is the most likely diagnosis?



A. Erythema nodosum
B. Necrobiosis lipoidica
C. Cutaneous Crohn disease
D. Necrotising fasciitis
E. Pyoderma gangrenosum

Answer: E.

Pyoderma gangrenosum is an uncommon neutrophilic dermatosis, which may occur in association with a range of diseases, including inflammatory bowel disease. It typically presents as a tender purple nodule, which rapidly breaks down and ulcerates and may heal with cribriform scarring. Immunosuppression may be needed until healed, although it generally does not recur. Erythema nodosum typically presents as tender nodules on shins, although can occur at any site. It is a reactive skin presentation and triggers include streptococcal infection, inflammatory bowel disease, rheumatoid arthritis, sarcoid and drugs. Lesions are often multiple and do not usually rapidly increase in size or ulcerate. Necrobiosis lipoidica is strongly associated with type 1 diabetes mellitus and typically presents as atrophic enlarging yellow-coloured plaques on the shins, which may ulcerate. A raised violaceous edge would be most unusual as atrophy is the hallmark. Cutaneous Crohn disease is rare and usually involves perineal or peristomal sites, presenting with infiltrative plaques, sinuses and fistulae. Necrotising fasciitis is rare and must be recognised and managed urgently as it is life-threatening. Patients are usually acutely unwell, febrile and in pain and rapidly evolving skin and deep soft tissue necrosis occurs, with crepitus evident on palpation. Bacterial cultures are positive and patients must be urgently managed through multidisciplinary supportive care, intravenous antibiotics and surgical débridement of necrotic tissue.

26.2. A 35-year-old woman with persistent severe acne vulgaris was referred for consideration of isotretinoin therapy. She had a history of anxiety and had not yet completed her family, so was concerned about possible side-effects. She had gathered information from friends and researching the internet, but was not sure if this was accurate. She arrived in clinic with a list of questions and hoped that her doctor could reassure her. Which of the following statements about isotretinoin therapy is true?

A. High cholesterol levels are a common side-effect
B. Conception should be avoided until 2 weeks after the treatment course
C. Mood disturbance during treatment occurs in most people
D. Dryness of lips and eyes is related to drug dose
E. Easy sunburning can persist for years after treatment

Answer: D.

Dryness of eyes and mouth is a common side-effect of isotretinoin through non-immunological dose-dependent direct toxicity. Isotretinoin commonly causes transient rise in triglycerides during treatment, but cholesterol is not usually significantly elevated. Conception must be avoided for at least one month after isotretinoin is discontinued as it is highly teratogenic and slowly eliminated. A range of mood disturbances has been reported in association with isotretinoin therapy, including an unproven risk of suicide. However, whilst mood monitoring during treatment is important, most patients do not experience lowering of mood and many find that their mood improves as their acne resolves. Isotretinoin can increase light sensitivity, even to wintertime or window glass–transmitted light. However, once the drug is stopped, light sensitivity will resolve and there is no evidence that it can persist long term.

26.3. A 22-year-old man presented with a 6-month history of a rash on his elbows, knees, shoulders and buttocks, which he described as being so itchy that he had not slept for months. He was otherwise well and on no medications, other than iron tablets. On examination there were excoriations at the affected sites but no other specific signs. A skin biopsy was taken from an affected area. What would you expect to see on H&E staining and direct immunofluorescence?

A. Sub-epidermal vesicles and granular IgA in the papillary dermis
B. Sub-epidermal vesicles and linear IgG at basement membrane
C. Intra-epidermal vesicles and granular IgA in the papillary dermis
D. Intra-epidermal vesicles and linear IgG at basement membrane
E. Sub-epidermal vesicles and linear IgA in the papillary dermis

Answer: A.

Sub-epidermal vesicles and granular IgA in the papillary dermis would be expected observations on skin biopsy analysis as the history and examination findings are highly suggestive of dermatitis herpetiformis and coeliac disease. The affected body sites and intense itch are typical and intact vesicles and blisters are not usually visible as they are de-roofed through scratching, with only excoriations remaining. Iron deficiency in an otherwise well 22-year-old male is unusual and strongly suggests malabsorption. Typical biopsy findings of lesional skin are of sub-epidermal vesicles in the dermal papillae, with a neutrophilic and eosinophilic infiltrate. Direct immunofluorescence shows granular IgA in the papillary dermis. The immunofluorescence findings can also be detected in the non-affected skin of the patient. Other investigations that can be performed include tissue transglutaminase and anti-endomysial antibodies, although characteristic biopsy findings are diagnostic. If the diagnosis of coeliac disease is uncertain, jejunal biopsy may be indicated. Dermatitis herpetiformis usually responds well to a gluten-free diet, with dapsone also being needed in some cases.

26.4. A 44-year-old woman attended the local dermatology clinic with a 2-month history of an itchy erythematous, scaly rash on her eyelids. She had no rash elsewhere and was fit and well, although she had a history of atopic dermatitis as a child. She was on no medication and worked as a nail technician at a beauty salon. On examination there were bilateral eczematous changes on both upper eyelids but no other abnormal signs. Allergic contact dermatitis was suspected. Patch testing was performed and showed a strong positive allergic reaction to a relevant allergen. Which of the following allergens is the most likely culprit?

A. Wool alcohol
B. Colophony
C. Paraphenylenediamine
D. Parabens
E. Dichromate

Answer: B.

Colophony is the likely allergen. It is present in sticking plasters, collodions and varnishes, and eyelid eczema can be an isolated manifestation of allergic contact dermatitis to colophony due to rubbing and touching eyelids. All of the provided answers are common allergens but the clues in this case are that she only had the eczematous rash on her eyelids and not elsewhere and that she worked as a nail technician.

26.5. A 38-year-old woman contacted her doctor as she wanted to get more information on how best to protect her 6-month-old baby from the sun as they were planning a sunny holiday. The doctor advised her about shade, hats and clothing and gave specific advice about sunscreens. Which of the following statements is true?

A. Sunblocks provide more sun protection than sunscreens
B. Sunscreens offer only 50%–60% of the sun protection factor (SPF) stated on the bottle
C. Reflectant sunscreens offer superior protection in the longer UVR wavelengths
D. Sunscreens should be avoided in babies as they commonly cause allergy
E. Sunscreen patch testing is the investigation of choice if allergy is suspected

Answer: C.

Reflectant sunscreen chemicals provide better protection against the longer UVA wavelengths than absorbent sunscreen chemicals. There is no such thing as a sunblock – all sunscreens offer partial protection at best. Studies have shown that with real-life sunscreen use, only 25%–33% of the stated sun protection factor (SPF) on the product is achieved. Sun protection for babies should mainly be through avoidance, shade and covering up, with sunscreens for unavoidable exposure at limited sites. However, sunscreens do not commonly cause allergy – if sunscreen reactions do occur they are usually due to irritancy, not allergy, with only the minority of reactions being true allergy or photoallergy. The investigation of choice for suspected sunscreen allergy is photopatch testing as photoallergic reactions may be missed on standard patch testing.

1 Examination of posture and gait

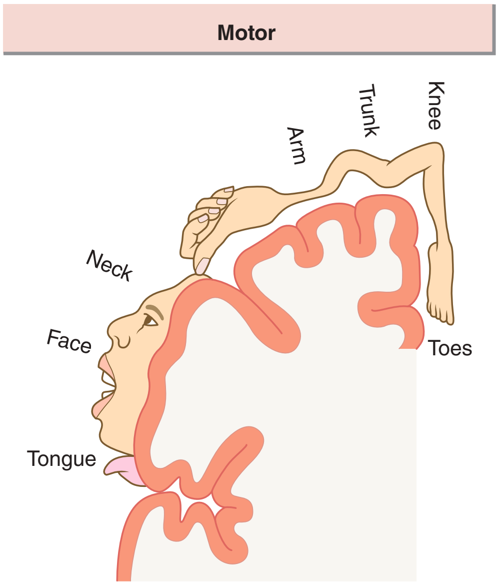
Procedure	Abnormality	Disease
Seated posture	Head and/or gaze deviation	Stroke with visual neglect
Pronator drift	Arm drifts downwards and pronates on affected side	Stroke with upper limb weakness
Rising from chair	Difficulty rising	Proximal muscle weakness or joint disorders
Gait initiation	Difficulty starting to walk, frozen	Cerebrovascular disease or parkinsonism
Standing posture	Stooped	Parkinsonism
Retropulsion/ anteropulsion	Postural instability	Parkinsonism
Arms during walking	Reduced arm swing	Parkinsonism or upper motor neuron lesion
	Enhanced tremor	Parkinsonism
	Dystonic posturing	Dystonia
Gait pattern	Circumduction (stiff leg moves outwards in ‘circular’ manner)	Hemiparesis, typically after established stroke
	‘Slapping’, high-stepping due to foot drop	L5 radiculopathy or common peroneal nerve lesion
	Narrow-based, short strides, freezing in doorways	Parkinsonism
	Stiff-legged, scissors gait	Spastic paraparesis (multiple sclerosis, vascular disease, spinal cord lesions)
	Wide-based, unsteady, unable to perform tandem gait	Cerebellar lesion
	Waddling gait	Myopathies with proximal weakness

4 Examination of cranial nerves

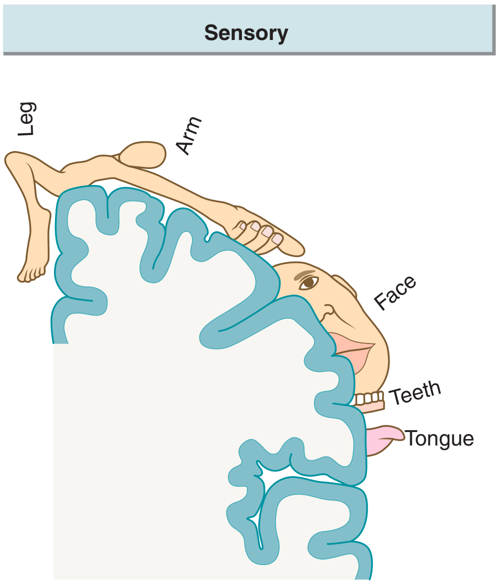
Nerve	Name	Tests
I	Olfactory	Ask patient about sense of smell (examine only if change is reported)
II	Optic	Visual acuity and colour vision Visual fields Pupillary responses Ophthalmoscopy
III	Oculomotor	Eyelids (ptosis) Pupil size, symmetry, reactions Eye movements
IV	Trochlear	Eye movements (superior oblique muscle)
V	Trigeminal	Facial sensation Corneal reflex Muscles of mastication
VI	Abducens	Eye movements (lateral rectus muscle)
VII	Facial	Facial symmetry and movements
VIII	Vestibulocochlear	Otoscopy Hearing Tuning fork tests (Rinne and Weber)
IX	Glossopharyngeal	Swallowing
X	Vagus	Palatal elevation (uvula deviates to side opposite lesion) Swallowing Cough (bovine) Speech
XI	Accessory	Look for wasting of trapezius/sternocleidomastoid Elevation of shoulders Turning head to right and left
XII	Hypoglossal	Look for wasting/fasciculation Tongue protrusion (deviates to side of lesion)

6 Root values of tendon reflexes

Reflex	Root value
Arm	
Biceps jerk	C5
Supinator jerk	C6
Triceps jerk	C7
Finger jerk	C8
Leg	
Knee jerk	L3/L4
Ankle jerk	S1



Motor cortex
(pre-central gyrus)



Somatic cortex
(post-central gyrus)

Motor and sensory homunculi. The motor and sensory homunculi illustrate the cortical areas serving each anatomical area within the pre-central (motor) and post-central (sensory) gyri.

The complexity of the brain differentiates us from other species, and its interactions with the spinal cord and peripheral nerves combine to allow us to perceive and react to the external world while maintaining a stable internal environment. The cerebral cortex provides a platform for processing information and forming a response, and in doing so, both forms and is affected by our personality and mental state.

Neurology has for too long been misperceived as a specialty in which intricate clinical examination and numerous investigations are required to diagnose obscure and untreatable conditions. In fact, nervous system disorders are common, accounting for 10% of the UK's general practice consultations, 20% of acute medical admissions and most chronic physical disability. The development of specific, effective treatments has made accurate diagnosis essential. Neurological management requires knowledge of a range of common conditions, which can be applied to individual patients after careful history-taking, with lesser contributions arising from targeted examination and considered investigation.

Pathological and anatomical localisation of symptoms and signs is important, but skill can be required to identify those *not* associated with neurological disease, differentiating patients requiring investigation and treatment from those who need reassurance.

Initially, it is important to exclude conditions that constitute neurological emergencies (Box 27.1). If the presentation is not an emergency, time can be taken to reach a diagnosis. The history should provide a hypothesis for the site and nature of the potential pathology, which a focused examination may refine, and direct appropriate further investigations. An informed discussion with the patient and family regarding diagnosis, management and prognosis may then take place.

Functional anatomy and physiology

Cells of the nervous system

The nervous system comprises billions of specialised cells, forming a spectacular network of connections. In addition to neurons, there are many types of glial cells. Astrocytes form the structural framework for neurons and control their biochemical environment, their foot processes adjoining small blood vessels and forming the blood–brain barrier (Fig. 27.1). Oligodendrocytes are responsible for the formation and maintenance of the myelin sheath, which surrounds axons and is essential for maintaining the speed and consistency of action potential propagation along axons. Peripheral nerves have axons invested in myelin made by Schwann cells. Microglial cells derive from monocytes/macrophages and play a role in fighting infection and removing damaged cells. Ependymal cells line the cerebral ventricles.

27.1 Neurological emergencies

- Status epilepticus (p. 1168)
- Stroke (if thrombolysis or mechanical thrombectomy available) (p. 1190)
- Guillain–Barré syndrome (p. 1238)
- Myasthenia gravis (if bulbar and/or respiratory) (p. 1239)
- Spinal cord compression (p. 1234)
- Subarachnoid haemorrhage (p. 1195)
- Neuroleptic malignant syndrome (p. 1281)

Generation and transmission of the nervous impulse

The role of the central nervous system (CNS) is to generate outputs in response to external stimuli and changes in internal conditions. The CNS has to maintain a delicate balance between responsivity to external stimuli and remaining stoic enough to remain stable in a rapidly changing environment. Each neuron receives input by synaptic transmission from dendrites (branched projections of other neurons), which sum to produce output in the form of an action potential that is then conducted along the axon, resulting in synaptic transmission to other neurons or, in the motor system, to muscle cells. Summation of the inputs causes net changes in the target neuron's electrochemical gradient, which, if large enough, will trigger an action potential. Communication between cells is by synaptic transmission that involves the release of neurotransmitters to interact with structures on the target cell's surface, including ion channels and other receptors (Fig. 27.2). At least 20 different neurotransmitters act at different sites in the nervous system, most of which are potentially amenable to pharmacological manipulation.

Fig. 27.2 Neurotransmission and neurotransmitters. (1) An action potential arriving at the nerve terminal depolarises the membrane and this opens voltage-gated calcium channels. (2) Entry of calcium causes the fusion of synaptic vesicles containing neurotransmitters with the pre-synaptic membrane and release of the neurotransmitter across the synaptic cleft. (3) The neurotransmitter binds to receptors on the post-synaptic membrane either (A) to open ligand-gated ion channels that, by allowing ion entry, depolarise the membrane and initiate an action potential (4), or (B) to bind to metabotropic receptors that activate an effector enzyme (e.g. adenylyl cyclase) and thus modulate gene transcription via the intracellular second messenger system, leading to changes in synthesis of ion channels or modulating enzymes. (5) Neurotransmitters are taken up at the pre-synaptic membrane and/or metabolised. (cAMP = cyclic adenosine monophosphate; DNA = deoxyribonucleic acid; mRNA = messenger ribonucleic acid)

Each neuronal cell body may receive synaptic input from thousands of other neurons. The synapsing neuron terminals are also subject to feedback regulation via receptor sites on the pre-synaptic membrane, modifying the release of transmitter across the synaptic cleft. In addition to such acute effects, some neurotransmitters produce long-term modulation of metabolic function or gene expression. This effect probably underlies more complex processes such as long-term memory.

Functional anatomy of the nervous system

Major components of the nervous system and their inter-relationships are depicted in Figure 27.3.

Cerebral hemispheres

The cerebral hemispheres coordinate the highest level of nervous function, the anterior half dealing with executive ('doing') functions and the posterior half constructing a perception of the environment. Each cerebral hemisphere has four functionally specialised lobes (Box 27.2 and Fig. 27.4), with some functions being distributed asymmetrically ('lateralised'), to produce cerebral dominance for functions such as motor control, speech or memory. Cerebral dominance aligns limb dominance with language function: in right-handed individuals the left hemisphere is almost always dominant, while around half of left-handers have a dominant right hemisphere.

Frontal lobes are concerned with executive function, movement, behaviour and planning. As well as the primary and supplementary motor cortex, there are specialised areas for control of eye movements, speech (Broca's area) and micturition.

The parietal lobes integrate sensory perception. The primary sensory cortex lies in the post-central gyrus of the parietal lobe. Much of the remainder is devoted to 'association' cortex, which processes and interprets input from the various sensory modalities. The supramarginal and angular gyri of the dominant parietal lobe form part of the language area (p. 1175). Close to these are regions dealing with numerical function. The non-dominant parietal lobe is concerned with spatial awareness and orientation.

27.2 Cortical lobar functions

		Effects of damage		
Lobe	**Function**	**Cognitive/behavioural**	**Associated physical signs**	**Positive phenomena**
Frontal	Personality Emotional control Social behaviour Contralateral motor control Language Micturition	Disinhibition Lack of initiation Antisocial behaviour Impaired memory Expressive dysphasia Incontinence	Impaired smell Contralateral hemiparesis Frontal release signs[1]	Seizures – often nocturnal with motor activity Versive head movements
Parietal: dominant	Language Calculation	Dysphasia Acalculia Dyslexia Apraxia[3] Agnosia[5]	Contralateral hemisensory loss Astereognosis[2] Agraphaesthesia[4] Contralateral homonymous lower quadrantanopia	Focal sensory seizures
Parietal: non-dominant	Spatial orientation Constructional skills	Neglect of contralateral side Spatial disorientation Constructional apraxia Dressing apraxia	Contralateral hemisensory loss Astereognosis[2] Agraphaesthesia[4] Contralateral homonymous lower quadrantanopia	Focal sensory seizures
Temporal: dominant	Auditory perception Language Verbal memory Smell Balance	Receptive aphasia Dyslexia Impaired verbal memory	Contralateral homonymous upper quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Temporal: non-dominant	Auditory perception Melody/pitch perception Non-verbal memory Smell Balance	Impaired non-verbal memory Impaired musical skills (tonal perception)	Contralateral homonymous upper quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Occipital	Visual processing	Visual inattention Visual loss Visual agnosia	Homonymous hemianopia (macular sparing)	Simple visual hallucinations (e.g. phosphenes, zigzag lines)

[1] Grasp reflex, palmomental response, pout response.
[2] Inability to determine three-dimensional shape by touch.
[3] Inability to perform complex movements in the presence of normal motor, sensory and cerebellar function.
[4] Inability to 'read' numbers or letters drawn on hand, with the eyes shut.
[5] Inability to recognise familiar objects, e.g. faces.

The temporal lobes contain the primary auditory cortex and primary vestibular cortex. On the inner medial sides lie the olfactory and parahippocampal cortices, which are involved in memory function. The temporal lobes also link intimately to the limbic system, including the hippocampus and the amygdala, which are involved in memory and emotional processing. The dominant temporal lobe also participates in language functions, particularly verbal comprehension (Wernicke's area). Musical processing occurs across both temporal lobes, rhythm on the dominant side and melody/pitch on the non-dominant.

The occipital lobes are responsible for visual interpretation. The contralateral visual hemifield is represented in each primary visual cortex, with surrounding areas processing specific visual submodalities such as colour, movement or depth, and the analysis of more complex visual patterns such as faces.

Deep to the grey matter in the cortices, and the white matter (composed of neuronal axons), are collections of cells known as the basal ganglia that are concerned with motor control; the thalamus, which is responsible for the level of attention to sensory perception; the limbic system, concerned with emotion and memory; and the hypothalamus, responsible for homeostasis, such as temperature and appetite control. The cerebral ventricles contain cerebrospinal fluid (CSF), which cushions the brain during cranial movement.

CSF is formed in the lateral ventricles and protects and nourishes the CNS. CSF flows from third to fourth ventricles and through foramina in the brainstem to dissipate over the surface of the CNS, eventually being reabsorbed into the cerebral venous system (see Fig. 27.57).

The brainstem

In addition to containing all the sensory and motor pathways entering and leaving the hemispheres, the brainstem houses the nuclei and projections of most cranial nerves, as well as other important collections of neurons in the reticular formation (Fig. 27.5). Cranial nerve nuclei provide motor control to muscles of the head (including face and eyes) and coordinate sensory input from the special sense organs and the face, nose, mouth, larynx and pharynx. They also relay autonomic messages, including pupillary, salivary and lacrimal functions. The reticular formation is mainly involved in control of conjugate eye movements, the maintenance of balance and arousal, and cardiorespiratory control.

The spinal cord

The spinal cord is the route for virtually all communication between the extracranial structures and the CNS. Afferent and efferent fibres are grouped in discrete bundles but collections of cells in the grey matter are responsible for lower-order motor reflexes and the primary processing of sensory information.

Sensory peripheral nervous system

The sensory cell bodies of peripheral nerves are situated just outside the spinal cord, in the dorsal root ganglia in the spinal exit foramina, while the distal ends of their neurons utilise various specialised endings for

the conversion of external stimuli into action potentials. Sensory nerves consist of a combination of large, fast, myelinated axons (which carry information about joint position sense and commands to muscles) and smaller, slower, unmyelinated axons (which carry information about pain and temperature, as well as autonomic function).

Motor peripheral nervous system

The anterior horns of the spinal cord comprise cell bodies of the lower motor neurons. To increase conduction speed, peripheral motor nerve axons are wrapped in myelin produced by Schwann cells. Motor neurons release acetylcholine across the neuromuscular junction, which changes the muscle end-plate potential and initiates muscle contraction.

The autonomic system

The autonomic system regulates the cardiovascular and respiratory systems, the smooth muscle of the gastrointestinal tract, and many exocrine and endocrine glands throughout the body. The autonomic system is controlled centrally by diffuse modulatory systems in the brainstem, limbic system, hypothalamus and frontal lobes, which are concerned with arousal and background behavioural responses to threat. Autonomic output divides functionally and pharmacologically into two divisions: the parasympathetic and sympathetic systems.

The motor system

A programme of movement formulated by the pre-motor cortex is converted into a series of excitatory and inhibitory signals in the motor cortex

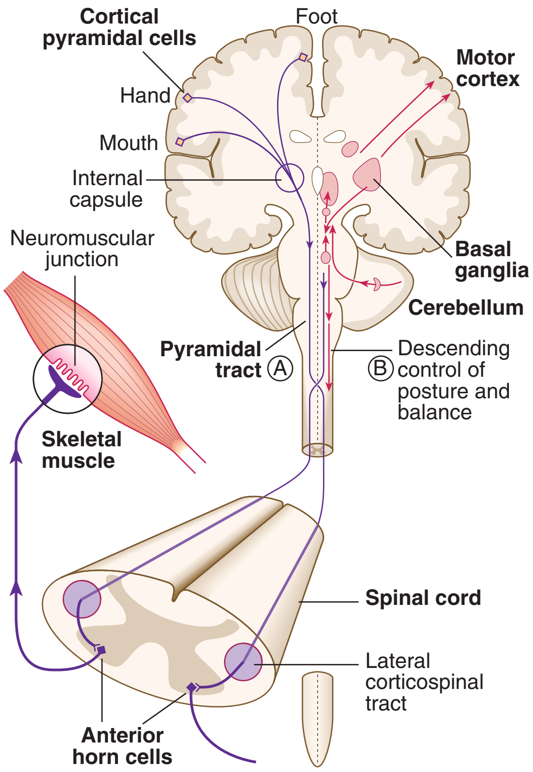

Fig. 27.6 The motor system. Neurons from the motor cortex descend as the pyramidal tract in the internal capsule and cerebral peduncle to the ventral brainstem, where most cross low in the medulla (A). In the spinal cord the upper motor neurons form the corticospinal tract in the lateral column before synapsing with the lower motor neurons in the anterior horns. The activity in the motor cortex is modulated by influences from the basal ganglia and cerebellum. Pathways descending from these structures control posture and balance (B).

that are transmitted to the spinal cord in the pyramidal tract (Fig. 27.6). This passes through the internal capsule and the ventral brainstem before crossing (decussating) in the medulla to enter the lateral columns of the spinal cord. The pyramidal tract ‘upper motor neurons’ synapse with the anterior horn cells of the spinal cord grey matter, which form the lower motor neurons.

Any movement necessitates changes in posture and muscle tone, sometimes in quite separate muscle groups to those involved in the actual movement. The motor system consists of a hierarchy of controls that maintain body posture and muscle tone, on which any movement is superimposed. In the grey matter of the spinal cord, the lowest order of the motor hierarchy controls reflex responses to stretch. Muscle spindles sense lengthening of the muscle; they provide the afferent side of the stretch reflex and initiate a monosynaptic reflex leading to protective or reactive muscle contraction. Inputs from the brainstem are largely inhibitory. Polysynaptic connections in the spinal cord grey matter control more complex reflex actions of flexion and extension of the limbs that form the basic building blocks of coordinated actions, but complete control requires input from the extrapyramidal system and the cerebellum.

Lower motor neurons

Lower motor neurons in the anterior horn of the spinal cord innervate a group of muscle fibres termed a ‘motor unit’. Loss of lower motor neurons causes loss of contraction within this unit, resulting in weakness and reduced muscle tone. Subsequently, denervated muscle fibres atrophy, causing muscle wasting, and depolarise spontaneously, causing ‘fibrillations’. Except in the tongue, these are usually perceptible only on electromyography (EMG; p. 1161). With the passage of time, neighbouring intact neurons sprout to provide re-innervation, but the neuromuscular junctions of the enlarged motor units are unstable and depolarise spontaneously, causing fasciculations (large enough to be visible). Fasciculations therefore imply chronic denervation with partial re-innervation.

Upper motor neurons

Upper motor neurons have both inhibitory and excitatory influence on the function of lower motor neurons in the anterior horn. Lesions affecting the upper motor neuron result in increased tone, most evident in the strongest muscle groups (i.e. the extensors of the lower limbs and the flexors of the upper limbs). The weakness of upper motor neuron lesions is conversely more pronounced in the opposing muscle groups. Loss of inhibition will also lead to brisk reflexes and enhanced reflex patterns of movement, such as flexion withdrawal to noxious stimuli and spasms of extension. The increased tone is more apparent during rapid stretching (‘spastic catch’) but may quickly give way with sustained tension (the ‘clasp-knife’ phenomenon). More primitive reflexes are also released, manifest as extensor plantar responses. Spasticity may not be present until some weeks after the onset of an upper motor neuron lesion.

The extrapyramidal system

Circuits between the basal ganglia and the motor cortex constitute the extrapyramidal system, which controls muscle tone, body posture and the initiation of movement (see Fig. 27.6). Lesions of the extrapyramidal system produce an increase in tone that, unlike spasticity, is continuous throughout the range of movement at any speed of stretch (‘lead pipe’ rigidity). Involuntary movements are also a feature of extrapyramidal lesions, and tremor in combination with rigidity produces typical ‘cogwheel’ rigidity. Extrapyramidal lesions also cause slowed and clumsy movements (bradykinesia), which characteristically reduce in size with repetition, as well as postural instability, which can precipitate falls.

The cerebellum

The cerebellum fine-tunes and coordinates movement initiated by the motor cortex, including articulation of speech. It also participates in the planning and learning of skilled movements through reciprocal connections with the thalamus and cortex. A lesion in a cerebellar hemisphere causes lack of coordination on the same side of the body. Cerebellar dysfunction impairs the smoothness of eye movements, causing nystagmus, and renders speech dysarthric. In the limbs, the initial movement is normal, but as the target is approached, the accuracy of the movement deteriorates, producing an ‘intention tremor’. The distances of targets are misjudged (dysmetria), resulting in ‘past-pointing’. The ability to produce rapid, accurate, regularly alternating movements is also impaired (dysdiadochokinesis). The central vermis of the cerebellum is concerned with the coordination of gait and posture. Disorders of this area therefore produce a characteristic ataxic gait (see below).

Vision

The neurological organisation of visual pathways is shown in Figure 27.7. Fibres from ganglion cells in the retina pass to the optic disc and then backwards through the lamina cribrosa to the optic nerve. Nasal optic nerve fibres (subserving the temporal visual field) cross at the chiasm but temporal fibres do not. Hence, fibres in each optic tract and further posteriorly carry representation of contralateral visual space. From the lateral geniculate nucleus, lower fibres pass through the temporal lobes on their way to the primary visual area in the occipital cortex, while the upper fibres pass through the parietal lobe.

Normally, the eyes move conjugately (in the same direction at the same speed), though horizontal convergence allows fusion of images at different distances. The control of eye movements begins in the cerebral hemispheres, particularly within the frontal eye fields, and the pathway then descends to the brainstem with input from the visual cortex, superior colliculus and cerebellum. Horizontal and vertical gaze centres in the

The pontine gaze centre projects to the 6th cranial nerve nucleus (B), which innervates the ipsilateral lateral rectus and projects to the contralateral 3rd nerve nucleus (and hence medial rectus) via the medial longitudinal fasciculus (MLF). Tonic inputs from the vestibular apparatus (C) project to the contralateral 6th nerve nucleus via the vestibular nuclei.

pons and mid-brain, respectively, coordinate output to the ocular motor nerve nuclei (3, 4 and 6), which are connected to each other by the medial longitudinal fasciculus (MLF) (Fig. 27.8). The MLF is particularly important in coordinating horizontal movements of the eyes. The resulting signals to extraocular muscles are supplied by the oculomotor (3rd), trochlear (4th) and abducens (6th) cranial nerves.

The pupillary size is determined by a combination of parasympathetic and sympathetic activity. Parasympathetic fibres originate in the Edinger–Westphal subnucleus of the 3rd nerve, and pass with the 3rd nerve to synapse in the ciliary ganglion before supplying the constrictor pupillae of the iris. Sympathetic fibres originate in the hypothalamus, pass down the brainstem and cervical spinal cord to emerge at T1, return up to the eye in association with the internal carotid artery, and supply the dilator pupillae.

Fig. 27.9 Areas of the cerebral cortex involved in the generation of spoken language.

Speech

Much of the cerebral cortex is involved in the process of forming and interpreting communicating sounds, especially in the dominant hemisphere (see Box 27.2). Decoding of speech sounds (phonemes) is carried out in the upper part of the posterior temporal lobe. The attribution of meaning, as well as the formulation of the language required for the expression of ideas and concepts, occurs predominantly in the lower parts of the anterior parietal lobe (the angular and supramarginal gyri). The temporal speech comprehension region is called Wernicke's area (Fig. 27.9). Other parts of the temporal lobe contribute to verbal memory, where lexicons of meaningful words are 'stored'. Parts of the non-dominant parietal lobe appear to contribute to non-verbal aspects of language in recognising meaningful intonation patterns (prosody).

The frontal language area is in the posterior end of the dominant inferior frontal gyrus known as Broca's area. This receives input from the temporal and parietal lobes via the arcuate fasciculus. The motor commands generated in Broca's area pass to the cranial nerve nuclei in the pons and medulla, as well as to the anterior horn cells in the spinal cord. Nerve impulses to the lips, tongue, palate, pharynx, larynx and respiratory muscles result in the series of ordered sounds comprising speech. The cerebellum also plays an important role in coordinating speech, and lesions of the cerebellum lead to dysarthria, where the problem lies in motor articulation of speech.

The somatosensory system

The body surface can be described by dermatomes, each dermatome being an area of skin in which sensory nerves derive from a single spinal nerve root (Fig. 27.10). Sensory information ascends in two anatomically discrete systems (Fig. 27.11). Fibres from proprioceptive organs and those mediating specific sensation (including vibration) enter the spinal cord at the posterior horn and pass without synapsing into the ipsilateral posterior columns. In contrast, fibres conveying pain and temperature sensory information (nociceptive neurons) synapse with second-order neurons that cross the midline in the spinal cord before ascending in the contralateral anterolateral spinothalamic tract to the brainstem.

The second-order neurons of the dorsal column sensory system cross the midline in the upper medulla to ascend through the brainstem. Here they lie just medial to the (already crossed) spinothalamic pathway. Brainstem lesions can therefore cause sensory loss affecting all modalities on the contralateral side of the body. Distribution of facial sensory loss due to brainstem lesions arises from the anatomy of

Fig. 27.10 **The areas supplied by specific levels of the spinal cord.** These are approximations and in practice there is much overlap. The clinical utility of these dermatomes has diminished somewhat with the advent of good magnetic resonance imaging of the spinal cord, but it remains important to ascertain the presence of a 'spinal level' of sensation, to remember the supply of the saddle area, and to note the cervical descent of some facial spinothalamic pathways. **A** Anterior. **B** Posterior.

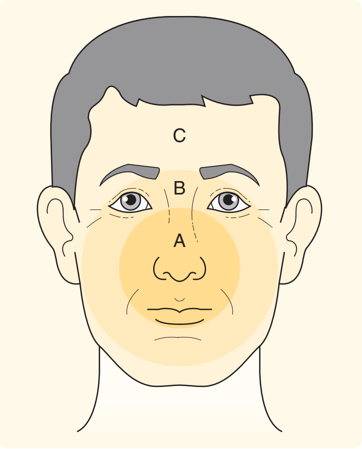

Fig. 27.12 Lesions in the inferior pons (A), medulla (B) and upper cervical cord (C) produce loss of pain and temperature sensation with an 'onion skin or Balaclava' distribution due to lesions in the descending trigeminal tract and nucleus. *From Yogarajah M, Lastri D, Octaviana F, Horton-Szar D. Crash course: neurologi. Elsevier Singapore: 2018.*

the trigeminal fibres within the brainstem. Fibres from the back of the face (near the ears) descend within the brainstem to the upper part of the spinal cord before synapsing, the second-order neurons crossing the midline and then ascending with the spinothalamic fibres. Fibres conveying sensation from more anterior areas of the face descend a shorter distance in the brainstem. Thus, sensory loss in the face from low brainstem lesions is in a 'balaclava helmet' distribution, as the longer descending trigeminal fibres are affected (Fig. 27.12). Both dorsal column and spinothalamic tracts end in the thalamus, relaying from there to the parietal cortex.

Pain

Pain is a complex perception that is only partly related to activity in nociceptor neurons (Fig. 9.5). Higher up, chronic and severe pain interacts extensively with mood and can exacerbate or be exacerbated by mood disorder, including depression and anxiety. Modification of psychological and psychiatric sequelae is a vital part of pain management (see Ch. 9).

Sphincter control

The sympathetic supply to the bladder arises from roots T11–L2 to synapse in the inferior hypogastric plexus, while the parasympathetic supply leaves from S2–4. In addition, a somatic supply to the external (voluntary) sphincter arises from S2–4, travelling via the pudendal nerves.

Storage of urine is maintained by inhibiting parasympathetic activity and thus relaxing the detrusor muscle of the bladder wall. Continence is also helped by simultaneous sympathetic- and somatic-mediated tonic contraction of the urethral sphincters. Voiding in adults is usually carried out under conscious control, which triggers relaxation of tonic inhibition on the pontine micturition centre from higher centres, leading to relaxation of the pelvic floor muscles and external and internal urethral sphincters, along with parasympathetic-mediated detrusor contraction.

Personality and mood

The physiology and pathology of mood disorders are discussed elsewhere (Ch. 29), but it is important to remember that any process affecting brain function may influence mood and affect. Conversely, mood disorder may have a significant effect on perception and function. It can be difficult to disentangle whether psychological and psychiatric changes are the cause or the effect of any neurological symptoms.

Sleep

The function of sleep is unknown but it is required for health. Sleep is controlled by the reticular activating system in the upper brainstem and diencephalon. It is composed of different stages that can be visualised on electroencephalography (EEG). As drowsiness occurs, normal EEG background alpha rhythm disappears and activity becomes dominated by deepening slow-wave activity. As sleep deepens and dreaming begins, the limbs become flaccid, movements are 'blocked' and EEG signs of rapid eye movements (REM) are superimposed on the slow wave. REM sleep persists for a short spell before another slow-wave spell starts, the cycle repeating several times throughout the night. REM phases lengthen as sleep progresses. REM sleep seems to be the most important part of the sleep cycle for refreshing cognitive processes, and REM sleep deprivation causes tiredness, irritability and impaired judgement.

Blood supply to the brain

The paired internal carotid and vertebral arteries supply blood to the brain. Each internal carotid artery bifurcates into the anterior and middle cerebral arteries, which supply the anterior cerebrum ('anterior circulation'). The vertebral arteries join to form the basilar artery (supplying the brainstem, cerebellum and pons), which bifurcates into the posterior cerebral arteries, which supply the posterior cerebrum ('posterior circulation') (Fig. 27.13). Communicating arteries connect the anterior with the posterior and the left with the right circulations. These anastomoses form the circle of Willis that, if complete, maintains cerebral circulation even if one carotid or vertebral artery is blocked. In health, autoregulation maintains a constant cerebral blood flow across a wide range of arterial blood pressures to meet the high cerebral metabolic activity. This autoregulatory mechanism can be disrupted after stroke. The venous system is formed by a collection of sinuses over the surface of the brain, which drain into the jugular veins (Fig. 27.14).

Localising lesions in the central nervous system

After taking a history and examining the patient, the clinician should have an idea of the nature and site of any pathology (see Box 27.10). Given the intricate anatomy of the brainstem, this section will dwell on the possible localisation in more detail (see Fig. 27.5).

Brainstem lesions typically present with symptoms due to cranial nerve, cerebellar and upper motor neuron dysfunction and are most commonly caused by vascular disease. Since the anatomy of the brainstem is very precisely organised, it is usually possible to localise the site of a lesion on the basis of careful history and examination in order to determine exactly which tracts/nuclei are affected, usually invoking the fewest number of lesions.

For example, in a patient presenting with sudden onset of upper motor neuron features affecting the right face, arm and leg in association with a left 3rd nerve palsy, the lesion will be in the left cerebral peduncle in the brainstem and the pathology is likely to have been a discrete stroke, as the onset was sudden. Examples of brainstem lesions are listed in Box 27.3. The effects of individual cranial nerve deficits are discussed elsewhere in this chapter in the sections on eye movements, and on facial weakness, sensory loss in brainstem lesions, dysphonia and dysarthria, and bulbar symptoms.

Investigation of neurological disease

Experienced clinicians make most neurological diagnoses on history alone, with a lesser contribution from examination and investigation. As investigations become more complex and more easily available, it is tempting to adopt a 'scan first, think later' approach to neurological symptoms. The frequency of 'false-positive' results, the wide range of normality and the negative implications for patients (unnecessary expense, inconvenience, discomfort and worry) necessitate a more thoughtful approach. Investigation may include assessment of structure (imaging) and function (neurophysiology). Neurophysiological testing has become so complex that in some countries it constitutes a separate specialty focusing on electroencephalography, evoked potentials, nerve conduction studies and electromyography.

Neuroimaging

Neurological imaging has traditionally allowed only assessment of structure but advances are allowing much more sophistication. Imaging modalities can use ionising radiation (plain X-rays, computed tomography (CT), CT perfusion (CTP), CT angiography, myelography and angiography), magnetic resonance (MR imaging (MRI), MR angiography (MRA)), ultrasound (Doppler imaging of blood vessels) and nuclear medicine techniques (single photon emission computed tomography (SPECT) and positron emission tomography (PET)). The uses and limitations of each of these are shown in Box 27.4. Different sequences for analysing MRI signals can provide helpful information for characterising tissues and pathologies (Box 27.5).

Advanced MR techniques, such as functional MRI (fMRI), MR spectroscopy or diffusion tensor imaging (DTI), can be used to assess brain metabolism and chemical compositions. This may be dynamic and can provide 'maps' of cortical function to help plan lesionectomy and epilepsy surgery. Similarly, MR spectroscopy can outline the chemical composition of specific regions, providing notions of whether lesions are ischaemic, neoplastic or inflammatory.

Perfusion of brain tissue can be demonstrated with CT after injection of contrast media (i.e. CT perfusion scanning). After ischaemic stroke, this technique can identify areas of brain with low perfusion that might be reversed with thrombolysis or thrombectomy.

Some degenerative neurological conditions cause functional rather than structural abnormalities that make metabolic and neurochemical assessment increasingly useful. PET scanning can display glucose metabolism in dementia and epilepsy. SPECT scanning uses the lipid-soluble properties of radioactive tracers to mark cerebral blood flow at the time of injection to help in investigating seizures. Dopaminergic pathway tracers can assess the integrity of the nigrostriatal pathway in patients with possible parkinsonism.

Head and orbit

Plain skull X-rays now have a very limited role in neurological disease. CT or MRI is needed for intracranial imaging. CT is good for demonstrating bone and calcification well. It will also detect abnormalities of the brain and ventricles, such as atrophy, tumours, cysts, abscesses, vascular lesions and hydrocephalus. Diagnostic yield may be improved by the use of intravenous contrast and thinner slicing but CT is not optimal for lesions of meninges, cranial nerves or subtle parenchymal changes.

MRI resolution is unaffected by bone and so is more useful in posterior fossa disease. Its sensitivity for cortical and white matter changes makes it the modality of choice in inflammatory conditions such as multiple sclerosis, for detecting strokes in the brainstem or cerebellum (when the CT is normal) and in the investigation of epilepsy. Different MRI techniques can selectively suppress signal from fluid or fat, for example, and so increase sensitivity for more subtle pathologies. Diffusion weighted MRI (DWI) can detect ischaemic stroke earlier than CT by highlighting oedematous brain tissue. Its use in hyperacute stroke is limited by longer scanning times and it may not show changes in up to one-third of stroke patients.

Examples of brain imaged by the various techniques are shown in Figure 27.15.

Cervical, thoracic and lumbar spine

X-rays are useful for imaging bony structures and can show destruction or damage to vertebrae, for example, but will provide no information about non-bony tissues, such as intervertebral discs, spinal cord and nerve roots. They have some usefulness in dynamic imaging, e.g. flexion/extension of the spine, in the assessment of instability. MRI has transformed spinal investigation, as it can give information not only about vertebrae and intervertebral discs but also about their effects on the spinal cord and nerve roots. Myelography (usually with CT) is a rarely used invasive technique requiring injection of contrast into the lumbar theca. While outlining the nerve roots and spinal cord provides some detail about abnormal structure, the accuracy and availability of MRI have reduced the need for it. Myelography may still be used where MRI is unavailable, contraindicated, or precluded by a patient's claustrophobia. Examples of the cervical spine imaged by plain X-rays, myelography and MRI are shown in Figure 27.16.

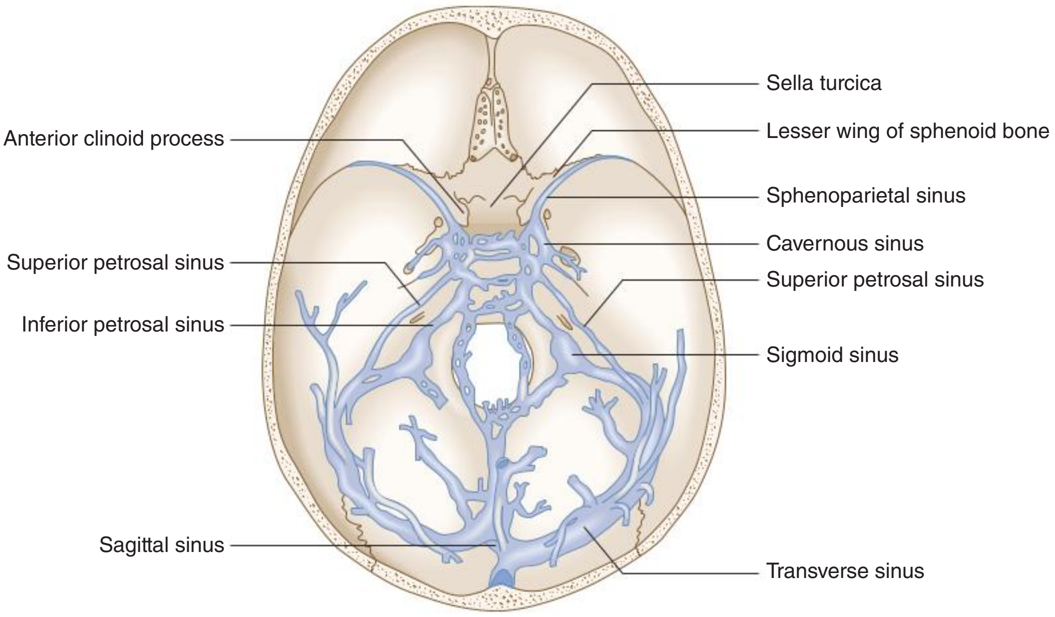

Fig. 27.14 **Veins of the brain.** *Adapted from R. Shane Tubbs (ed). Anatomy, imaging and surgery of the intracranial dural venous sinuses. Elsevier; 2020. https://doi.org/10.1016/B978-0-323–65377-0.00017–9.*

27.3 Major focal brainstem lesions

Site of lesions	Clinical features
Midbrain	Ipsilateral 3rd palsy Contralateral upper motor neuron 7th palsy Contralateral hemiplegia
Dorsal mid-brain (tectum)	Vertical gaze palsy Convergence disorders Convergence retraction nystagmus Pupillary and lid disorders
Pons	Ipsilateral 6th palsy Ipsilateral lower motor neuron 7th palsy Contralateral hemiplegia
Medulla (lateral medullary syndrome)	Ipsilateral 5th, 9th, 10th, 11th palsy Ipsilateral Horner syndrome Ipsilateral cerebellar signs Contralateral spinothalamic sensory loss Vestibular disturbance

Blood vessels

Imaging of the extra- and intracranial blood vessels can identify the cause of a stroke. CT angiography (CTA) can identify large artery occlusion amenable to thrombectomy. CTA and intra-arterial angiography can detect arteriovenous malformations (AVMs) or aneurysms requiring surgery. Doppler ultrasound can screen for carotid stenosis, dissection or generalised atherosclerosis (see Fig. 27.31).

Neurophysiological testing

Electroencephalography

The electroencephalogram (EEG) detects electrical activity arising in the cerebral cortex via electrodes placed on the scalp to record the amplitude and frequency of the resulting waveforms. With closed eyes, the normal background activity is 8–13 Hz (known as alpha rhythm), most prominent occipitally and suppressed on eye opening. Other frequency bands seen over different parts of the brain in different circumstances are beta (faster than 13/sec), theta (4–8/sec) and delta (slower than 4/sec). Normal EEG patterns evolve with age and alertness; lower frequencies predominate in the very young and during sleep.

In recent years digital technology has allowed longer, cleaner EEG recordings that can be analysed in a number of ways and recorded alongside contemporaneous video of any clinical ‘event’. Meanwhile, the development of intracranial recording allows more sensitive monitoring via surgically placed electrodes in and around lesions to help increase the efficacy and safety of epilepsy surgery.

Abnormal EEGs result from a number of conditions. Examples include an increase in fast frequencies (beta) seen with sedating drugs such as benzodiazepines, or marked focal slowing noted over a structural lesion such as a tumour or an infarct. Improved quality and accessibility of imaging have made EEG redundant in lesion localisation, except in the specialist investigation of epilepsy (p. 1199). EEG remains useful in progressive and continuous disorders such as reduced consciousness, encephalitis and certain dementias, such as Creutzfeldt–Jakob disease.

Since sleep induces marked changes in cerebral activity, EEG can be useful in diagnosis of sleep disturbances. In paroxysmal disorders such as epilepsy, EEG is at its most useful when it captures activity during one of the events in question. Over 50% of patients with epilepsy have a normal ‘routine’ EEG but, conversely, the presence of epileptiform features does not of itself make a diagnosis. Up to 5% of some normal populations may demonstrate epileptiform discharges on EEG, preventing its use as a screening test for epilepsy, most notably in younger patients with a family history of epilepsy. In view of this, the EEG should not be used where epilepsy is merely ‘possible’.

Therefore the EEG in epilepsy is predominantly used for classification and prognostication, but in some patients can help localise the seat of epileptiform discharges when surgery is being considered. During a seizure, high-voltage disturbances of background activity (‘discharges’) are often noted. These may be generalised, as in the 3 Hz ‘spike and wave’ of childhood absence epilepsy, or more focal, as in localisation-related epilepsies (Fig. 27.17). Techniques such as hyperventilation or photic stimulation can be used to increase the yield of epileptiform changes, particularly in the generalised epilepsy syndromes. While some argue that it is possible to detect ‘spikes’ and ‘sharp waves’ to lend support to a clinical diagnosis, these are non-specific and therefore not diagnostic, and can lead an unwary clinician to err in ascribing other symptoms to epilepsy.

27.4 Imaging techniques for the nervous system

Technique	Applications	Advantages	Disadvantages	Comments
X-ray/CT	Plain X-rays, CT, CTP, CTA Radiculography Myelography Intra-arterial angiography	Widely available Relatively cheap Relatively quick	Ionising radiation Contrast reactions Invasive (myelography and angiography)	X-rays: used for fractures or foreign bodies CT: first line for stroke Intra-arterial angiography: gold standard for vascular lesions
MRI	Structural imaging MRA Functional MRI MR spectroscopy	High-quality soft tissue images, useful for posterior fossa and temporal lobes No ionising radiation Non-invasive	Expensive Less widely available MRA images blood flow, not vessel anatomy Claustrophobic Pacemakers are a contraindication Contrast (gadolinium) reactions	Functional MR and spectroscopy: mainly research tools
Ultrasound	Doppler Duplex scans	Cheap Quick Non-invasive	Operator-dependent Poor anatomical definition	Screening tool to assess need for carotid endarterectomy
Radioisotope	Isotope brain scan SPECT PET	In vivo imaging of functional anatomy (ligand binding, blood flow)	Poor spatial resolution Ionising radiation Expensive Not widely available	Isotope scans: obsolete SPECT: useful in movement disorders, epilepsy and dementias PET: mainly research tool

(CT = computed tomography; CTA = computed tomographic angiography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PET = positron emission tomography; SPECT = single photon emission computed tomography)

Nerve conduction studies

Electrical stimulation of a nerve causes an impulse to travel both efferently and afferently along the underlying axons. Nerve conduction studies (NCS) make use of this, recording action potentials as they pass along peripheral nerves and (with motor nerves) as they pass into the muscle belly. Digital recording has enhanced sensitivity and reproducibility of these tiny potentials. By measuring the time taken to traverse a known distance, it is possible to calculate nerve conduction velocities (NCVs). Healthy nerves at room temperature will conduct at a speed of 40–50 m/sec. If the recorded potential is smaller than expected, this provides evidence of a reduction in the overall number of functioning axons. Significant slowing of conduction velocity, in contrast, suggests impaired conduction due to peripheral nerve demyelination. Such changes in NCS

Fig. 27.18 Motor nerve conduction tests. Electrodes (R) on the muscle (abductor pollicis here) record the compound muscle action potential (CMAP) after stimulation at the median nerve at the wrist (S_1) and from the elbow (S_2). The velocity from elbow to wrist can be determined if the distance between the two stimulating electrodes (d) is known. A prolonged L_1 (L = latency) would be caused by dysfunction distally in the median nerve (e.g. in carpal tunnel syndrome). A prolonged L_2 is caused by slow nerve conduction (as in demyelinating neuropathy). The F wave is a small delayed response that appears when the electrical signal travels backwards to the anterior horn cell, sparking a second action potential in a minority of fibres (see text). (NCV = nerve conduction velocity)

may be diffuse (as in a hereditary demyelinating peripheral neuropathy), focal (as in pressure palsies) or multifocal (e.g. Guillain–Barré syndrome, mononeuritis multiplex). The information gained can allow the disease responsible for peripheral nerve dysfunction to be better deduced (see Box 27.99).

Stimulation of motor nerves allows for the recording of compound muscle action potentials (CMAPs) over muscles (Fig. 27.18). These are around 500 times larger than sensory nerve potentials, typically around 1–20 millivolts. Since a proportion of stimulated impulses in motor nerves will ‘reflect’ back from the anterior horn cell body (forming the ‘F’ wave), it is also possible to obtain some information about the condition of nerve roots.

Repetitive nerve stimulation (RNS) at 3–15/sec provides consistent CMAPs in healthy muscle. In myasthenia gravis (p. 1239), however, where there is partial blockage of acetylcholine receptors, there is a diagnostic fall (decrement) in CMAP amplitude. In contrast, an increasing

CMAP with high-frequency RNS is seen in Lambert–Eaton myasthenic syndrome (p. 1240).

Electromyography

Electromyography (EMG) is usually performed alongside NCS and involves needle recording of muscle electrical potential during rest and contraction. At rest, muscle is electrically silent but loss of nerve supply causes muscle membrane to become unstable, manifest as fibrillations, positive sharp waves ('spontaneous activity') or fasciculations. Motor unit action potentials are recorded during muscle contraction. Axonal loss or destruction will result in fewer motor units. Resultant sprouting of remaining units will lead to increasing size of each individual unit on EMG. Myopathy, in contrast, causes muscle fibre splitting, which results in a large number of smaller units on EMG. Other abnormal activity, such as myotonic discharges, may signify abnormal ion channel conduction, as in myotonic dystrophy or myotonia congenita.

Specialised single-fibre electromyography (SFEMG) can be used to investigate neuromuscular junction transmission. Measuring 'jitter' and 'blocking' can identify the effect of antibodies in reducing the action of acetylcholine on the receptor.

Evoked potentials

The cortical response to visual, auditory or electrical stimulation can be measured on an EEG as an evoked potential (EP). If a stimulus is provided – e.g. to the eye – the tiny EEG response can be discerned when averaging 100–1000 repeated stimuli. Assessing the latency (the time delay) and amplitude can give information about the integrity of the relevant pathway. MRI now provides more information about CNS pathways, thus reducing reliance on EPs. In practice, visual evoked potentials (VEPs) are most commonly used to help differentiate CNS demyelination from small-vessel white-matter changes (Fig. 27.19).

Magnetic stimulation

Central conduction times can also be measured using electromagnetic induction of action potentials in the cortex or spinal cord by the local application of specialised coils. Again, MRI has made this technique largely redundant, other than for research.

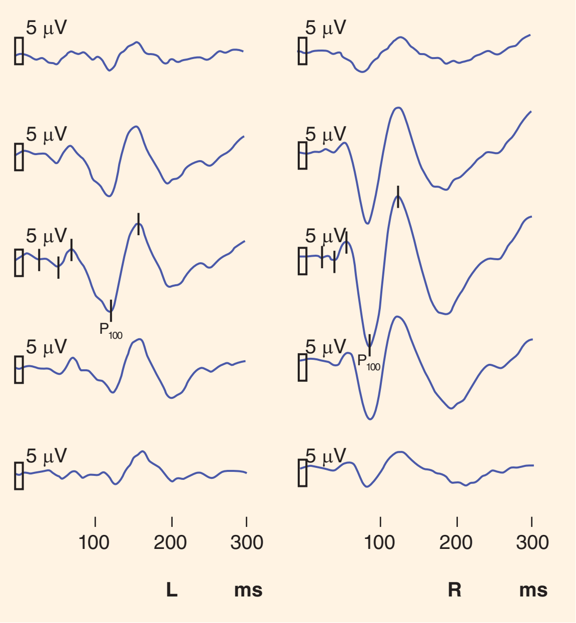

Fig. 27.19 Visual evoked potential (VEP) recording. The abnormality is in the left hemisphere, with delay in latency and a reduction in signal of the P_{100}.

Routine blood tests

Many systemic conditions that can affect the nervous system can be identified by simple blood tests. Nutritional deficiencies, metabolic disturbances, inflammatory conditions or infections may all present or be associated with neurological symptoms, and basic blood tests (full blood count, erythrocyte sedimentation rate, C-reactive protein, biochemical screening) may provide clues. Specific blood tests will be highlighted in the relevant subsections of this chapter. Human immunodeficiency virus (HIV) infection is an important cause of neurological disease and the clinician should test all patients for this infection.

Immunological tests

Recent developments have seen a host of new immune-mediated conditions emerge in clinical neurology, with antibody targets ranging from muscle and neuromuscular junction disturbance (causing weakness and muscle pain) to specific neuroglial cell surface molecules such as ion channels (causing cognitive decline, epilepsy and psychiatric changes). Examples of autoantibodies that aid diagnosis and may play a disease-causing role include AChR antibodies (myasthenia gravis), aquaporin-4 and MOG antibodies (neuromyelitis optica), NMDAR, Lgi1 and CASPR2 antibodies (autoimmune encephalitis). Many of these antibodies to neural/glial cell surface antigens are specifically associated with individual neurological syndromes. Many other antibodies against intracellular antigens have also been described, in particular in association with paraneoplastic syndromes, although it is less clear if these antibodies play a causal role in mediating disease.

Genetic testing

Relevant subsections will detail the increasing numbers of inherited neurological conditions that can now be diagnosed by DNA analysis (p. 51). These include diseases caused by increased numbers of trinucleotide repeats, such as Huntington disease, myotonic dystrophy and some types of spinocerebellar ataxia. Mitochondrial DNA can also be sequenced to diagnose relevant disorders. Next-generation sequencing technologies including exome sequencing and whole genome sequencing are increasingly employed to identify undiagnosed genetic disease, but expertise is required in their interpretation (see Ch. 3).

Lumbar puncture

Lumbar puncture (LP) is the technique used to obtain both a CSF sample and an indirect measure of intracranial pressure. After local anaesthetic injection, a needle is inserted between lumbar spinous processes (usually between L3 and L4) through the dura and into the spinal canal. Intracranial pressure can be deduced (if patients are lying on their side) and CSF removed for analysis. CSF pressure measurement is important in the diagnosis and monitoring of idiopathic intracranial hypertension. In this condition, the LP itself is therapeutic.

CSF is normally clear and colourless, and the tests that are usually performed include a naked eye examination of the CSF and centrifugation to determine the colour of the supernatant (yellow, or xanthochromic, some hours after subarachnoid haemorrhage; p. 1195). Measurement of absorption of specific light wavelengths helps quantify the amount of haem metabolites in CSF. Routine analysis involves a cell count, as well as glucose and protein concentrations.

CSF assessment is important in investigating infections (meningitis or encephalitis), subarachnoid haemorrhage and inflammatory conditions. Normal values and abnormalities found in specific conditions are shown in Box 27.6.

More sophisticated analysis allows measurement of antibody formation solely within the CNS (oligoclonal bands), genetic analysis (e.g. polymerase chain reaction (PCR) for herpes viruses or tuberculosis), immunological tests (NMDAR, paraneoplastic antibodies), immunophenotyping

27.6 How to interpret cerebrospinal fluid results

	Normal	Subarachnoid haemorrhage	Multiple sclerosis	Carcinomatous/ lymphomatous meningitis	AIDP[1]
Pressure	50–250 mmH_2O	Increased	Normal	Normal/increased	Normal
Colour	Clear	Blood-stained Xanthochromic	Clear	Clear/xanthochromic	Clear
Red cell count ($\times 10^6$/L)	0–4	Raised	Normal	Normal/elevated	Normal
White cell count ($\times 10^6$/L)	0–4	Normal/slightly raised	0–50 lymphocytes	0–400 lymphocyte	0–50 (< 5 in 85%)
Glucose	> 50%–60% of blood level	Normal	Normal	Normal/decreased	Normal
Protein	< 0.45 g/L	Increased	Normal/increased	Normal/increased	Increased[2]
Microbiology	Sterile	Sterile	Sterile	Sterile/cytology may be helpful	Sterile
Oligoclonal bands	Negative	Negative	Often positive	Uncertain	Matched bands (serum and CSF)

	Acute bacterial meningitis	Partially treated bacterial meningitis[2]	Viral meningitis[2]	Cryptococcal meningitis in HIV[1]	Tuberculous meningitis
Pressure	Normal/increased	Normal/increased	Normal	Elevated often very high	Normal/increased
Colour	Cloudy	Clear/cloudy	Clear	Clear/cloudy	Clear/cloudy
Red cell count ($\times 10^6$/L)	Normal	Normal	Normal	Normal	Normal
White cell count ($\times 10^6$/L)	1000–5000 polymorphs	Normal to raised; mixed cells	10–2000 lymphocytes	20–200 mainly lymphocytes	50–5000 lymphocytes
Glucose	Decreased	Normal/decreased	Normal	Normal/decreased	Decreased
Protein	Increased	Normal/increased	Normal/increased	Normal/increased	Increased
Microbiology	Organisms on Gram stain and/or culture	Greater chance of no growth	Sterile/virus detected	India ink positive (around 50%); cryptococcal antigen/culture	Ziehl–Neelsen/auramine stain or tuberculosis culture positive
Oligoclonal bands	Can be positive	Can be positive	Can be positive	Uncertain	Can be positive

[1] See Chapter 14 for more detail on findings in HIV infection.
[2] Cerebrospinal fluid findings in bacterial and viral meningitis are variable, and this table shows only the most common patterns.
(AIDP = acute inflammatory demyelinating polyneuropathy; HIV = human immunodeficiency virus)

by fluorescence-activated cell sorting (FACS) and cytology (to detect malignant cells).

If there is a cranial space-occupying lesion causing raised intracranial pressure, LP presents a theoretical risk of downward shift of intracerebral contents, a potentially fatal process known as coning. Consequently, LP is contraindicated if there is any clinical suggestion of raised intracranial pressure (papilloedema), depressed level of consciousness, or focal neurological signs suggesting a cerebral lesion, until imaging (by CT or MRI) has excluded a space-occupying lesion or hydrocephalus. When there is a risk of local haemorrhage (thrombocytopenia, disseminated intravascular coagulation or anticoagulant treatment), then caution should be exercised or specific measures should be taken. LP can be safely performed in patients on low-dose aspirin or low-dose heparin. UK guidelines advise considering pausing other antiplatelet agents for a period before elective LP (e.g. 7 days for clopidogrel). LP may be unsafe in patients who are fully anticoagulated due to the increased risk of epidural haematoma, and haematology advice should be sought.

About 30% of LPs are followed by a postural headache, due to reduced CSF pressure. The frequency of headache can be reduced by using smaller or atraumatic needles. Rarer complications involve transient radicular pain, and pain over the lumbar region during the procedure. Aseptic technique renders secondary infections such as meningitis extremely rare.

Biopsy

Biopsies of nervous tissue (peripheral nerve, muscle, meninges or brain) are occasionally required for diagnosis.

Nerve biopsy can help in the investigation of peripheral neuropathy. Usually, a distal sensory nerve (sural or radial) is targeted. Histological examination can help identify underlying causes, such as vasculitides or infiltrative disorders like amyloid. Nerve biopsy should not be undertaken lightly since there is an appreciable morbidity; it should be reserved for cases where the diagnosis is in doubt after routine investigations and where it will influence management.

Muscle biopsy is performed more frequently and is indicated for the differentiation of myositis and myopathies. These conditions can usually be distinguished by histological examination, and enzyme histochemistry can be useful when mitochondrial diseases and storage diseases are suspected. The quadriceps muscle is most commonly biopsied but other muscles may also be sampled if they are involved clinically. Although pain and infection can follow the procedure, these are less of a problem than after nerve biopsy. Imaging and clinical examination may help guide and determine biopsy site.

Brain biopsy is required when imaging fails to clarify the nature of intracerebral lesions, e.g. in unexplained degenerative diseases such as unusual cases of dementia and in patients with brain tumours. Some biopsies are performed stereotactically through a burr hole in the skull. Nevertheless, haemorrhage, infection and death still occur and brain biopsy should be considered only if a diagnosis is otherwise elusive. Discussion between neurologist, neuroradiologist, neurosurgeon and neuropathologist is important to ensure maximal diagnostic yield of these samples.

Biopsy of other organs can be useful in the diagnosis of systemic disorders presenting as neurological problems, such as tonsillar biopsy (prion diseases), or rectal or fat biopsy (for assessment of amyloid).

Presenting problems in neurological disease

While history is important in all medical specialties, it is especially key in neurology, where many neurological diagnoses have no confirmatory test. History-taking allows doctor and patient to get to know one another; many neurological diseases follow chronic paths and this may be the first of many such consultations. It also allows the clinician to obtain information about the patient's affect, cognition and psychiatric state.

History-taking is a highly active process. While there are generic templates (Box 27.7), each individual story will follow its own course, and diagnostic considerations during the history will guide further questioning.

It is important to be clear about what patients mean by certain words. They may find it difficult to describe symptoms: for instance, weakness may be called 'numbness', while there are many possible interpretations of 'dizziness'. These must be clarified; even in emergency situations, a clear, accurate history is the foundation of any management plan. While the story should come primarily from the patient, input from eye-witnesses and family members is crucial if the patient is unable to provide details or if there has been loss of consciousness. This need for corroboration and clarification means the telephone is as important as any investigation.

The aim of the history is to address two key issues: (1) *where is the lesion?* and (2) *what is the lesion?* (Box 27.8). These should remain uppermost in the doctor's mind while the history is being elicited, especially in older people (Box 27.9). Some common combinations of symptoms may suggest particular locations for a lesion (Box 27.10). Enquiry about handedness is important; lateralisation of the dominant hand helps designate the dominant hemisphere, which in turn may help to localise any pathologies, or to plan rehabilitation or treatment strategies in asymmetrical disorders such as stroke or Parkinson disease.

Epidemiology must be borne in mind. How likely is it that this particular patient has any specific condition under consideration? For example, a 20-year-old with right-sided headache and tenderness will not have temporal arteritis, but this is an important possibility if such symptoms present in a 78-year-old female. Global epidemiology is important and endemic infectious agents and travel history should always be considered.

Determining the evolution, speed of onset and progression of a disease is important (Box 27.11). For example, if right-hand weakness occurred overnight, it would suggest a stroke in an older person or an acute entrapment neuropathy in a younger one. Evolution over several days, however, might make demyelination (multiple sclerosis) a possible diagnosis, or perhaps a subdural haematoma if the weakness was preceded by a head injury in an older person taking warfarin. Progression over weeks might bring an intracranial mass lesion or motor neuron disease into the differential. Slow progression over a year or so, with difficulty in using the hand, could suggest a degenerative process such as Parkinson disease. The impact on day-to-day activities, such as walking, climbing stairs and carrying out fine hand movements, should also be established in order to gauge the level of associated disability.

Estimates of the frequency and duration of specific events are essential when taking details of a paroxysmal disorder such as migraine and epilepsy. Vague terms such as 'a lot' or 'sometimes' are unhelpful, and it can assist the patient if choices are given to estimate numbers, such as once a day, week or month.

Many neurological symptoms are not explained by typical neurological disease. Describing these as 'functional' is less pejorative, more acceptable to patients and more in keeping with modern understanding of these symptoms than 'psychogenic' or 'hysterical'. Functional symptoms require considerable experience in diagnosis and are frequently missed.

Headache and facial pain

Most headaches are chronic disorders but acute presentation of headaches is an important aspect of emergency medical care. Headache may be divided into primary (benign) or secondary, and most patients, whether presenting in clinic or as emergencies, have primary syndromes (see Box 10.13). The emergency clinical assessment of headaches is dealt with on page 222.

Ocular pain

Assuming that ocular disease (such as acute glaucoma) has been excluded, ocular pain may be due to trigeminal autonomic cephalalgias (TACs) or, rarely, inflammatory or infiltrative lesions at the apex of the orbit

27.7 How to take a neurological history

Introduction

- Age and sex
- Handedness

Presenting complaint

- Symptoms (clarify: see text)
- Overall pattern: intermittent or persistent?
- If intermittent, how often do symptoms occur and how long do they last?
- Speed of onset: seconds, minutes, hours, days, weeks, months, years, decades?
- Better, worse or the same over time?
- Associated symptoms (including non-neurological)
- Disability caused by symptoms
- Change in walking
- Difficulty with fine hand movements, e.g. writing, fastening buttons, using cutlery
- Effect on work, family life and leisure

Background

- Previous neurological symptoms and whether similar to current symptoms
- Previous medical history
- Domestic situation
- Driving licence status
- Medications (current and at time of symptom onset)
- Alcohol/smoking habits
- Recreational drug and other toxin exposure
- Family history and developmental history
- What are patient's thoughts/fears/concerns?

27.8 The key diagnostic questions

Where is the lesion?

- Is it neurological?
- If so, to which part of the nervous system does it localise?
  Central versus peripheral

What is the lesion?

- Hereditary or congenital
- Acquired:
    - Traumatic
    - Infective
    - Neoplastic
    - Degenerative
    - Inflammatory or immune-mediated
    - Vascular – if vascular, to which vascular territory does it localise?
    - Functional

27.9 Neurological examination in old age

- **Pupils**: tend to be smaller, making fundoscopy more difficult.
- **Limb tone**: more difficult to assess because of poor relaxation and concomitant joint disease.
- **Ankle reflexes**: may be absent.
- **Gait assessment**: more difficult because of concurrent musculoskeletal disease and pre-existing neurological deficits.
- **Sensory testing**: especially difficult when there is cognitive impairment.
- **Vibration sense**: may be reduced distally in the legs.

27.10 How to 'localise' neurological disease

Combination of symptoms/signs	Probable site	Possible pathology	Other important information
Painless loss of hemilateral function	Cerebral cortex	Usually vascular, inflammatory or neoplastic	Associated systemic symptoms Tempo of evolution
Pyramidal weakness of all four limbs or both legs, bladder signs, sensory loss	Spinal cord	Usually vascular, inflammatory, infective, or neoplastic	Associated systemic symptoms Tempo of evolution Travel history Endemic infections
Cranial nerve lesions, with limb pyramidal signs or sensory loss ± sphincter disturbance	Brainstem Mid-brain Pons Medulla	Usually vascular or inflammatory Rarely neoplastic or infective	Associated systemic symptoms Tempo of evolution Travel history Endemic infections
Visual loss + pyramidal signs and/or cerebellar signs	Widespread cerebral lesions	Usually inflammatory	Tempo of evolution
Weakness and/or sensory loss in a combination of individual peripheral nerves	Several peripheral nerves ('mononeuritis multiplex')	Usually inflammatory or diabetic, rarely infective, such as human immunodeficiency virus	Associated systemic symptoms
Weakness with widespread LMN and UMN signs	Upper and lower motor neurons	Motor neuron disease Cervical myeloradiculopathy	Associated localised cervical symptoms
Distal loss of sensation and/or weakness	Generalised peripheral nerves	See causes of neuropathy (p. 1235)	Associated systemic symptoms

(LMN/UMN = lower/upper motor neuron)

27.11 The evolution of symptoms

Onset	Evolution	Possible causes
Sudden (minutes to hours)	Stable/improvement	Vascular (stroke/transient ischaemic attack (TIA)) Nerve entrapment syndromes Functional
Gradual	Progressive over days	Inflammation Infection
Gradual	Progressive over weeks to months	Neoplastic/paraneoplastic
Gradual	Progressive over months to years	Genetic Degenerative

or the cavernous sinus, when 3rd, 4th, 5th or 6th cranial nerve involvement is usually evident. Ocular pain and headache are also discussed on page 1251.

Facial pain

Pain in the face can be due to dental or temporomandibular joint problems. Acute sinusitis is usually apparent from other features of sinus congestion/infection and may cause localised pain over the affected sinus, but is almost never the explanation for persistent facial pain or headache.

Facial pain is not uncommon in migraine but some syndromes can present solely with facial pain. The most common neurological causes of facial pain are trigeminal neuralgia, herpes zoster (shingles) and post-herpetic neuralgia, all characterised by their extreme severity. In trigeminal neuralgia, the patient describes bouts of brief (seconds), lancinating pain ('electric shocks'), most frequently felt in the second and third divisions of the nerve and often triggered by talking or chewing. Facial shingles most commonly affects the first (ophthalmic) division of the trigeminal nerve, and pain usually precedes the rash. Post-herpetic neuralgia may follow, typically a continuous burning pain throughout the affected territory, with marked sensitivity to light touch (allodynia) and resistance to treatment. Destructive lesions of the trigeminal nerve usually cause numbness rather than pain.

Dizziness, blackouts and 'funny turns'

Acute onset of dizziness or blackouts will present to the acute medical department. In neurological practice, it is common to deal with patients presenting with a history of multiple events. While detailed questioning will be dealt with in the relevant section (p. 221), the neurologist will have to tease out the pattern of each of the different attack types experienced by the patient to be able to form a treatment and investigation plan, one of the challenges of clinical neurology.

Status epilepticus

Status epilepticus is seizure activity not resolving spontaneously, or recurrent seizure with no recovery of consciousness in between. Persisting seizure activity has a recognised mortality and is a medical emergency.

Diagnosis is usually clinical and can be made on the basis of the description of prolonged rigidity and/or clonic movements with loss of awareness. As seizure activity becomes prolonged, movements may become more subtle. Cyanosis, pyrexia, acidosis and sweating may occur, and complications include aspiration, hypotension, cardiac arrhythmias and renal or hepatic failure.

In patients with pre-existing epilepsy, the most likely cause is a fall in antiseizure drug levels. In de novo status epilepticus, it is essential to exclude precipitants such as infection (meningitis, encephalitis), neoplasia and metabolic derangement (hypoglycaemia, hyponatraemia or hypocalcaemia). Treatment and investigation are outlined in Box 27.12.

Coma

Coma and loss of consciousness usually present to the acute medical admissions department (p. 234). Clarification of cause and prognosis may require specialist neurological input.

Delirium

Delirium describes cortical dysfunction and replaces the older term 'acute confusional state'. It has a range of primary causes, and given its role in precipitating acute admission, it is covered in detail on page 1346.

27.12 Management of status epilepticus

Initial

- Ensure airway is patent; give oxygen to prevent cerebral hypoxia
- Check pulse, blood pressure, glucose and respiratory rate
- Secure intravenous access and initiate ECG monitoring
- Send blood for:
    - Glucose, urea and electrolytes, calcium and magnesium, liver function, antiseizure drug levels
    - Full blood count and coagulation screen
    - Storing a sample for future analysis (e.g. drug misuse)
- If seizures continue for > 5 mins: give midazolam 10 mg buccally or nasally or lorazepam 4 mg IV if access available or diazepam 10 mg rectally or IV if necessary; repeat *once only* after 15 mins
- Correct any metabolic trigger, e.g. hypoglycaemia, thiamine deficiency (give thiamine before glucose if suspected)

Ongoing

If seizures continue after 30 mins

- IV infusion with one of:
    - Levetiracetam: 60 mg/kg (max dose 4500 mg) over 10 minutes
    - Phenytoin: 15 mg/kg at 50 mg/min (with cardiac monitoring, risk of hypotension and bradycardia)
    - Sodium valproate: 20–30 mg/kg IV at 40 mg/min
    - Phenobarbital: 10 mg/kg at 100 mg/min
- Cardiac monitor and pulse oximetry:
    - Monitor neurological condition, blood pressure, respiration; check blood gases
- If severe renal dysfunction with eGFR less than 30 mL/min/1.73 m^2, avoid levetiracetam; sodium valproate is then drug of first choice

If seizures still continue after 30–60 mins

- Transfer to intensive care:
    - Start treatment for refractory status with intubation, ventilation and general anaesthesia using propofol or thiopental
    - EEG monitor

Once status controlled

- Commence longer-term antiseizure medication with one of:
    - Levetiracetam 1000–1500 mg IV, oral/nasogastric tube twice daily (adjust for renal impairment and start 10–12 hours after loading dose)
    - Sodium valproate 10 mg/kg IV over 3–5 mins, then 800–2000 mg/day
    - Phenytoin: give loading dose (if not already used as above) of 15 mg/kg, infuse at < 50 mg/min, then 300 mg/day
    - Carbamazepine 400 mg by nasogastric tube, then 400–1200 mg/day
- Investigate cause

(ECG = electrocardiogram; EEG = electroencephalogram; eGFR = estimated glomerular filtration rate; IV = intravenous)

Amnesia

Memory disturbance is a common symptom. In the absence of significant functional impairment (e.g. inability to work, dyspraxias, loss of daily function), many patients will prove to have benign memory dysfunction related to age, mood or psychiatric disorders. Investigation and treatment of the dementias are discussed elsewhere (p. 1293).

Temporary loss of memory may be due to a transient delirium related to infection, the post-ictal period after seizure, or transient global amnesia. These are usually distinguished on the basis of the history. Transient amnesia resulting directly from a seizure (transient epileptic amnesia) is a rare result of temporal lobe epilepsy.

Transient global amnesia

Transient global amnesia (TGA) predominantly affects middle-aged people, with an abrupt, discrete loss of anterograde memory function lasting up to a few hours. During the episode, patients are unable to record new memories, resulting in repetitive questioning, the hallmark of this condition. Consciousness is preserved and patients may perform even complex motor acts normally. During the attack there is retrograde amnesia for the events of the past few days, weeks or years. After 4–6 hours, memory function and behaviour return to normal but the patient has persistent, complete amnesia for the duration of the attack itself. There are no seizure markers and, unlike epileptic amnesia, transient global amnesia recurs in only around 10%–20% of cases. A vascular aetiology is unlikely (TGA is not a risk factor for subsequent vascular disease) and amnesia may be due to a benign process similar to migraine, occurring in the hippocampus. TGA causes no physical signs and, provided there is a typical history (which requires a witness), no investigation is necessary and patients may be reassured.

Persistent amnesia

Serious neurological disease must be excluded in patients with persistent memory disturbance, although many will prove to have benign symptoms. Symptoms corroborated by relatives or colleagues are likely to be more significant than those noted by the patient only. Where poor concentration is at the heart of cognitive deterioration, it is more likely to be due to an underlying mood disorder.

It is important to assess the timing of onset and to establish which aspects of memory are affected. Complaints of getting lost or of losing complex abilities are more pathological than word-finding difficulties. Disturbance of episodic or working memory (previously called ‘short-term memory’) must be distinguished from semantic memory (memory for concept-based knowledge unrelated to specific experiences). Episodic memory is selectively impaired in Korsakoff syndrome (often secondary to alcohol) or bilateral temporal lobe damage. It can also be seen in conjunction with other types of dementia. Progressive deterioration over months suggests an underlying dementia, and a full medical assessment must be performed to detect any underlying medical problem.

It is important to identify and treat depression in patients with memory loss. Depression may present as a ‘pseudo-dementia’, with concentration and memory impairment as dominant features, and this is often reversible with antidepressant medication. Any patient with dementia (particularly of Alzheimer type) may develop depression in the early stages of their illness, however. Specific causes of progressive dementia, with their investigation and treatment, are described elsewhere (p. 1293).

Weakness

The assessment of weakness requires the application of basic anatomy, physiology and some pathology to the interpretation of the history and clinical findings. Points to consider are shown on Figure 27.20 and in Boxes 27.13 and 27.14. The pattern and evolution of weakness and the clinical signs provide clues to the site and nature of the lesion.

It is important to establish whether the patient has loss of power rather than reduced sensation or generalised fatigue. Pain may restrict movement and thus mimic weakness. Paradoxically, sensory neglect may leave patients unaware of severe weakness.

Patients with parkinsonism may complain of weakness; extrapyramidal signs of rigidity (cogwheel or lead pipe) and bradykinesia should be evident, and a resting tremor (usually asymmetrical) may provide a further clue. Simple observation of the patient walking into the consulting room may be diagnostic and is as important as formal strength testing. Movement restricted by pain should be apparent, and other features (contractures, wasting, fasciculations, abnormal movements/postures) all provide diagnostic clues.

Weakness is a common symptom arising without an underlying degenerative or destructive cause (functional symptom). Functional weakness does not conform to typical patterns, and the signs in Box 27.13 are absent. Clinical examination is often variable (e.g. the patient can walk but appears to have no leg movement when assessed on the couch), and strength may appear to ‘give way’, with the patient able to achieve full power for brief bursts, which does not occur in disease. Hoover sign is useful to confirm functional weakness and relies on eliciting the normal

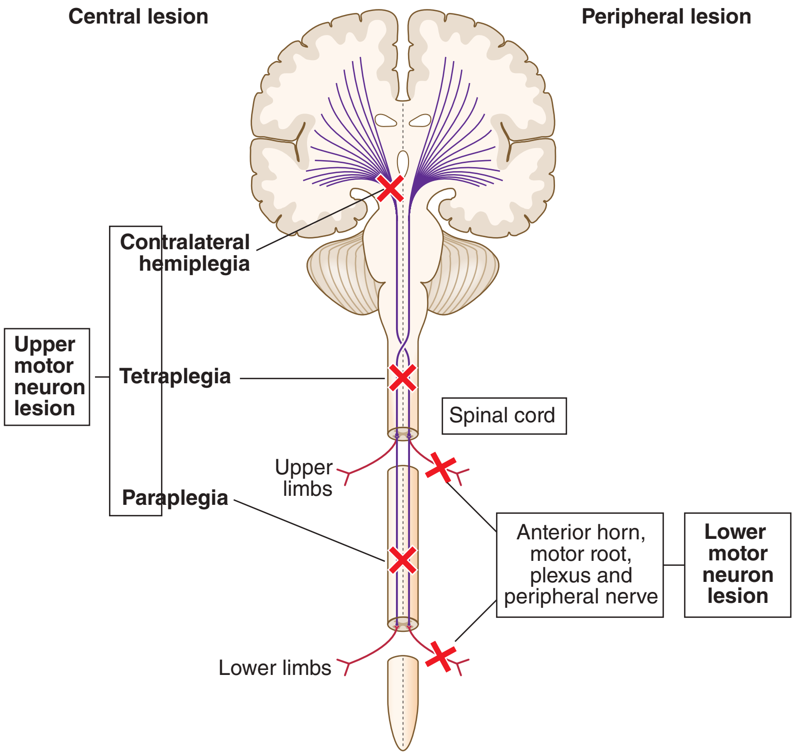

Fig. 27.20 Patterns of motor loss according to the anatomical site of the lesion.

27.13 Distinguishing signs in upper versus lower motor neuron syndromes

	Upper motor neuron lesion	Lower motor neuron lesion
Inspection	Normal (may be wasting in chronic lesions)	Wasting, fasciculation
Tone	Increased with clonus (hypotonic in early stroke or acute spinal cord lesion)	Normal or decreased, no clonus
Pattern of weakness	Preferentially affects extensors in arms, flexors in leg Hemiparesis, paraparesis or tetraparesis	Typically focal, in distribution of nerve root or peripheral nerve, with associated sensory changes
Deep tendon reflexes	Increased	Decreased/absent
Plantar response	Extensor (Babinski sign)	Flexor

phenomenon of simultaneous hip extension when the contralateral hip flexes. In functional weakness, hip extension weakness may be seen; this then returns to full strength when contralateral hip flexion is tested. This sign may be demonstrated to the patient in a non-confrontational manner, to show that potential limb power is intact.

Facial weakness

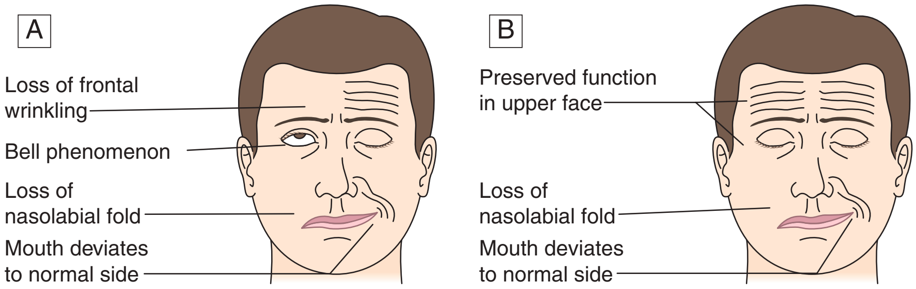
Facial nerve palsy (Bell palsy)

One of the most common causes of facial weakness is Bell palsy, a lower motor neuron lesion of the 7th (facial) nerve, affecting all ages and both sexes. It is classically associated with herpesvirus infections or Lyme disease and is more common following upper respiratory tract infections, during pregnancy and in patients with diabetes, immunosuppression and hypertension. It can occur in human immunodeficiency virus at the time of seroconversion.

27.14 How to assess weakness

Clinical finding	Likely level of lesion/diagnosis
Pattern and distribution	
Isolated muscles	Radiculopathy or mononeuropathy
Both limbs on one side (hemiparesis)	Cerebral hemisphere, less likely cord or brainstem
One limb	Neuronopathy, plexopathy, cord/brain
Both lower limbs (paraparesis)	Spinal cord; look for a sensory level
Fatigability	Myasthenia gravis
Bizarre, fluctuating, not following anatomical rules	Functional
Signs	
Upper motor neuron	Brain/spinal cord
Lower motor neuron	Peripheral nervous system
Evolution of the weakness	
Sudden and improving	Stroke/mononeuropathy
Evolving over months or years	Meningioma, cervical spondylotic myelopathy
Gradually worsening over days or weeks	Cerebral mass, demyelination, infection
Associated symptoms	
Absence of sensory involvement	Motor neuron disease, myopathy, myasthenia

The lesion is within the facial canal. Symptoms usually develop subacutely over a few hours, with pain around the ear preceding the unilateral facial weakness. Patients often describe the face as 'numb' but there is no objective sensory loss (except to taste, if the chorda tympani is involved). Hyperacusis may occur if the nerve to stapedius is involved and impairment of parasympathetic fibres may cause diminished salivation and tear secretion. Examination reveals an ipsilateral lower motor neuron facial nerve palsy (no sparing of forehead muscles; Fig. 27.21). Vesicles in the ear or on the palate may indicate varicella zoster virus (VZV) reactivation (see p. 338). A clinical search for signs of other causes of lower motor neuron facial nerve weakness, such as parotid or scalp lesions, trauma or skull base lesions, is justified.



A
Loss of frontal wrinkling
Bell phenomenon
Loss of nasolabial fold
Mouth deviates to normal side
B
Preserved function in upper face
Loss of nasolabial fold
Mouth deviates to normal side

Fig. 27.21 Unilateral facial nerve VII paralysis. **A** Involvement of the lower motor neuron of the facial nerve results in an inability to close the affected eyelid. The patient's gaze points upward, with exposure of the conjunctiva below the cornea (Bell palsy). **B** An upper motor neuron lesion showing sparing of the upper facial nerve function allows the patient to close the eyelid. *From Pemde H, Datta V, Harish K. Clinical and practical paediatrics. 2nd ed. Elsevier: 2022.*

Glucocorticoids improve recovery rates if started within 72 hours of onset, but antiviral drugs are not effective. Artificial tears applied regularly prevent corneal drying, and taping the eye shut overnight helps prevent exposure keratitis and corneal abrasion. Patients unable to close the eye should be referred urgently to an ophthalmologist. About 80% of patients recover spontaneously within 12 weeks. Plastic surgery may be considered for the minority left with facial disfigurement after 12 months. Recurrence is unusual and should prompt further investigation. Aberrant re-innervation may occur during recovery, producing unwanted facial movements, such as eye closure when the mouth is moved (synkinesis) or 'crocodile tears' (tearing during salivation).

Unlike Bell palsy, lesions with an upper motor neuron origin may spare the upper face so that eyebrow raising and eye closure are preserved (see Fig. 27.21). Cortical lesions may cause a facial weakness either in isolation or with associated hemiparesis and speech difficulties.

Sensory disturbance

Sensory symptoms are common and frequently benign. Patients often find sensory symptoms difficult to describe and sensory examination is difficult for both doctor and patient. While neurological disease can cause sensory symptoms, systemic disorders can also be responsible. Tingling in both hands and around the mouth can occur as the result of hyperventilation or hypocalcaemia. When there is dysfunction of the relevant cerebral cortex, the patient's perception of the wholeness or actual presence of the relevant part of the body may be distorted.

Numbness and paraesthesia

The history may give the best clues to localisation and pathology. Certain common patterns are recognised: in migraine, the aura may consist of spreading tingling or paraesthesia, followed by numbness evolving over 20–30 minutes over one half of the body, often splitting the tongue. Sensory loss caused by a stroke or transient ischaemic attack (TIA) occurs much more rapidly and is typically negative (numbness) rather than positive (tingling). Rarely, unpleasant paraesthesia of sensory epilepsy spreads within seconds. The sensory alteration of inflammatory spinal cord lesions often ascends from one or both lower limbs to a distinct level on the trunk over hours to days, and can give rise to a feeling of constriction, sometimes described as 'being hugged'. Sensory change can occur as a manifestation of anxiety or as part of a functional neurological disorder. In such cases, the distribution usually neither conforms to a known anatomical pattern nor fits with any typical neurological disease. Care must be taken in diagnosing functional sensory problems; a careful history and examination will ensure there is no other objective neurological deficit.

Sensory neurological examination needs to be undertaken and interpreted with care because the findings depend, by definition, on subjective reports. The reported distribution of sensory loss can be useful, however, when combined with the coexisting deficits of motor and/or cranial nerve function (Fig. 27.22).

Sensory loss in peripheral nerve lesions

Here the symptoms are usually of sensory loss and paraesthesia. Single nerve lesions cause disturbance in the sensory distribution of the nerve, whereas in diffuse neuropathies the longest neurons are affected first, giving a characteristic 'glove and stocking' distribution. If smaller nerve fibres are preferentially affected (e.g. in diabetic neuropathy), temperature and pin-prick (pain) are reduced, whilst vibration sense and proprioception (modalities served by the larger, well-myelinated, sensory nerves) may be relatively spared. In contrast, vibration and proprioception are particularly affected if the neuropathy is demyelinating in character, producing symptoms of tightness and swelling with impairment of proprioception and vibration sensation.

Sensory loss in nerve root lesions

These typically present with pain as a prominent feature, either within the spine or in the limb plexuses. Pain is often felt in the myotome rather than the dermatome. The nerve root involved may be deduced from the dermatomal pattern of sensory loss, although overlap may lead to this being smaller than expected.

Sensory loss in spinal cord lesions

Transverse lesions of the spinal cord produce loss of all sensory modalities below that segmental level, although the clinical level may only be manifest 2–3 segments lower than the anatomical site of the lesion. Very often, there is a band of paraesthesia or hyperaesthesia at the top of the area of sensory loss. Clinical examination may reveal dissociated sensory loss, i.e. different patterns in the spinothalamic and dorsal columnar pathways. If the transverse lesion is vascular due to anterior spinal artery thrombosis, the spinothalamic pathways may be affected while the posterior one-third of the spinal cord (the dorsal column modalities) may be spared.

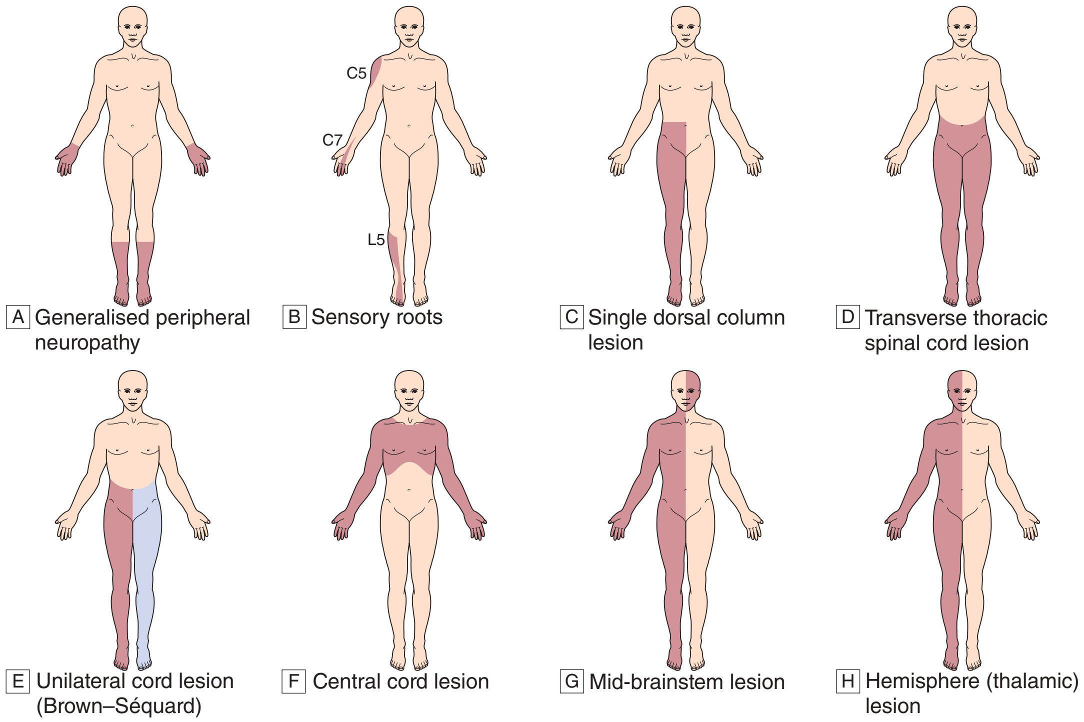
Lesions damaging one side of the spinal cord will produce loss of spinothalamic modalities (pain and temperature) on the opposite side, and of dorsal column modalities (joint position and vibration sense) on the same side of the body – the Brown–Séquard syndrome (see Fig. 27.22E).

Lesions in the centre of the spinal cord (such as syringomyelia: see Box 27.95 and Fig. 27.64) spare the dorsal columns but involve the spinothalamic fibres crossing the cord from both sides over the length of the lesion. There is no sensory loss in segments above and below the lesion; this is described as 'suspended' sensory loss. There is sometimes reflex loss at the level of the lesion if afferent fibres of the reflex arc are affected.

An isolated lesion of the dorsal columns is not uncommon in multiple sclerosis. This produces a characteristic unpleasant, tight feeling over the limb(s) involved and, while there is no loss of pin-prick or temperature sensation, the associated loss of proprioception may severely limit function of the affected limb(s).

Sensory loss in brainstem lesions

Lesions in the brainstem can be associated with sensory loss but the distribution depends on the site of the lesion. A lesion limited to the



A Generalised peripheral neuropathy
B Sensory roots
C Single dorsal column lesion
D Transverse thoracic spinal cord lesion
E Unilateral cord lesion (Brown–Séquard)
F Central cord lesion
G Mid-brainstem lesion
H Hemisphere (thalamic) lesion

Fig. 27.22 Patterns of sensory loss. **A** Generalised peripheral neuropathy. **B** Sensory roots: some common examples. **C** Single dorsal column lesion (proprioception and some touch loss). **D** Transverse thoracic spinal cord lesion. **E** Unilateral cord lesion (Brown–Séquard): ipsilateral dorsal column (and motor) deficit and contralateral spinothalamic deficit. **F** Central cord lesion: 'cape' distribution of spinothalamic loss. **G** Mid-brainstem lesion: ipsilateral facial sensory loss and contralateral loss on body below the vertex. **H** Hemisphere (thalamic) lesion: contralateral loss on one side of face and body.

trigeminal nucleus or its sensory projections will cause ipsilateral facial sensory disturbance. For example, pain resembling trigeminal neuralgia can be seen in patients with multiple sclerosis. The anatomy of the trigeminal connections means that lesions in the medulla or spinal cord can give rise to 'balaclava helmet' patterns of sensory loss. Sensory pathways running up from the spinal cord can also be damaged in the brainstem, resulting in simultaneous sensory loss in arm(s) and/or leg(s).

Sensory loss in hemispheric lesions

The temporal, parietal and occipital lobes receive sensory information regarding the various modalities of touch, vision, hearing and balance (see Box 27.2). The initial points of entry into the cortex are the respective primary cortical areas (see Fig. 27.4). Damage to any of these primary areas will result in reduction or loss of the ability to perceive that particular modality: 'negative' symptomatology. Abnormal excitation of these areas can result in a false perception ('positive' symptoms), the most common of which is migrainous visual aura (flashing lights or teichopsia).

Cortical lesions are more likely to cause a mixed motor and sensory loss. Substantial lesions of the parietal cortex (as in large strokes) can cause severe loss of proprioception and may even abolish conscious awareness of the existence of the affected limb(s), known as neglect; this can be difficult to distinguish from paralysis. Pathways are so tightly packed in the thalamus that even small lacunar strokes can cause isolated contralateral hemisensory loss.

Neuropathic pain

Neuropathic pain is a positive neurological symptom caused by dysfunction of the pain perception apparatus, in contrast to nociceptive pain, which is secondary to pathological processes such as inflammation. Neuropathic pain has distinctive features and typically provokes a very unpleasant, persistent, burning sensation. There is often increased sensitivity to touch, so that light brushing of the affected area causes exquisite pain (allodynia). Painful stimuli are felt as though they arise from a larger area than that touched, and spontaneous bursts of pain may also occur. Pain may be elicited by other modalities (allodynia) and is considerably affected by emotional influences. The most common causes of neuropathic pain are diabetic neuropathies, trigeminal and post-herpetic neuralgias, and trauma to a peripheral nerve. Treatment of these syndromes can be difficult. Drugs that modulate various parts of the nociceptive system, such as gabapentin, carbamazepine or tricyclic antidepressants, may help. Localised treatment (topical treatment or nerve blocks) sometimes succeeds but may increase the sensory deficit and worsen the situation. Electrical stimulation has occasionally proved successful.

Abnormal movements

Disorders of movement lead to either extra, unwanted movement (hyperkinetic disorders) or too little movement (hypokinetic disorders) (Box 27.15). In either case, the lesion often localises to the basal ganglia, although some tremors are related to cerebellar or brainstem disturbance. Functional movement disorders are common and may mimic all of the organic syndromes below. The most important hypokinetic disorder is Parkinson disease. Parkinsonism is a clinical description of a collection of symptoms, including tremor, bradykinesia and rigidity. While the history is always important, observation is clearly vital; much of the skill in diagnosing movement disorders lies in pattern recognition. Once it is established whether the problem is hypo- or hyperkinetic, the next task is to categorise the movements further, accepting that there is often overlap. Videoing the movements (with the patient's consent), so that they can be shown to a movement disorder expert, may provide a quick diagnosis in cases of uncertainty.

Tremor

Tremor is caused by alternating agonist/antagonist muscle contractions and produces a rhythmical oscillation of the body part affected. In the assessment of tremor, the position, body part affected, frequency and amplitude should be considered, as these provide diagnostic clues (Box 27.16).

Other hyperkinetic syndromes

Non-rhythmic involuntary movements include chorea, athetosis, ballism, dystonia, myoclonus and tics. They are categorised by clinical appearance, and coexistence and overlap are common, such as in choreoathetosis.

Chorea

Chorea (from the Greek word 'dance') refers to abrupt, brief, irregular, purposeless involuntary movements, appearing fidgety and clumsy and affecting different areas. They suggest disease in the caudate nucleus (as in Huntington disease) and are a common complication of levodopa treatment for Parkinson disease. Other causes are shown in Box 27.17.

27.15 Movement disorders

Description	Features	Examples
Hypokinetic disorders		
Parkinsonism	Akinesia	Idiopathic Parkinson disease
	Rigidity	Other degenerative syndromes
	Tremor	Drug-induced
	Loss of postural reflexes	(See Box 27.64)
	Other features depending on cause	
Catatonia	Mutism Sustained posturing and waxy flexibility	Usually psychiatric; if neurological, is most commonly of vascular origin
Hyperkinetic disorders		
Tremor	Rhythmical oscillation of body part (see Box 27.16)	Essential tremor Parkinson disease Drug-induced
Chorea	Abrupt, brief, irregular, involuntary movements	Huntington disease Drug-induced
Tics	Stereotyped, repetitive movements, briefly suppressible	Tourette syndrome
Myoclonus	Shock-like muscle jerks	Epilepsy Hypnic jerks Focal cortical disease
Dystonia	Sustained muscle contraction causing abnormal postures ± tremor	Genetic Generalised dystonic syndromes Focal dystonias in adults (e.g. torticollis)
Others	Various	Paroxysmal hyperkinetic dyskinesias Hemifacial spasm Tardive syndromes

Athetosis

Slower, writhing movements of the limbs are often combined with chorea and have similar causes.

Ballism

This more dramatic form of chorea causes often violent flinging movements of one limb (monoballism) or one side of the body (hemiballism). The lesion localises to the contralateral subthalamic nucleus and the most common cause is stroke.

Dystonia

Sustained involuntary muscle contraction causes abnormal postures or movement. It may be generalised (usually in childhood-onset genetic syndromes) or, more commonly, focal/segmental (such as in torticollis, when the head is twisted repeatedly to one side). Some dystonias occur only with specific tasks, such as writer's cramp or other occupational 'cramps'. Dystonic tremor is associated, is asymmetrical and of large amplitude.

Myoclonus

Myoclonus consists of brief, isolated, random jerks of muscle groups. This is physiological at the onset of sleep (hypnic jerks). Similarly, a

27.17 Causes of chorea

Hereditary

- Huntington disease (HD) and HD-like syndromes
- Wilson disease
- Neuroacanthocytosis
- Dentato-rubro-pallidoluysian atrophy
- Benign hereditary chorea
- Paroxysmal dyskinesias

Cerebral birth injury (including kernicterus)

Cerebral trauma

Drugs

- Levodopa (long-term with Parkinson disease)
- Antipsychotics
- Antiseizure medications
- Oral contraceptive

Metabolic

- Disorders affecting thyroid, parathyroid, glucose, sodium, calcium and magnesium balance
- Pregnancy

Autoimmune

- Post-streptococcal (Sydenham chorea)
- Antiphospholipid antibody syndrome
- Autoimmune encephalitis
- Systemic lupus erythematosus

Structural lesions of basal ganglia (usually caudate)

- Vascular
- Demyelination
- Brain tumour
- Infection

27.16 Causes and characteristics of tremors

	Body part affected	Position	Frequency	Amplitude	Character
Physiological	Both arms > legs	Posture, movement	High	Small (fine)	Enhanced by anxiety, emotion, drugs, toxins
Parkinsonism	Unilateral or asymmetrical	Rest	Low (3–4 Hz)	Moderate	Typically pill-rolling, thumb and index finger, other features of parkinsonism
	Arm > leg, chin, never head	Postural and re-emergent may occur			
Essential tremor	Bilateral arms, head	Movement	High (8–10 Hz)	Low to moderate	Family history; 50% respond to alcohol
Dystonic	Head, arms, legs	Posture	Variable	Variable	Other features of dystonia, often jerky tremors
Functional	Any	Any	Variable	Variable	Distractible

myoclonic jerk is a component of the normal startle response, which may be exaggerated in some rare (mostly genetic) disorders. Myoclonus may occur in disorders of the cerebral cortex, such as some forms of epilepsy. Alternatively, myoclonus can arise from subcortical structures or, more rarely, from segments of the spinal cord.

Tics

Tics are stereotyped repetitive movements, such as blinking, winking, head shaking or shoulder shrugging. Unlike dyskinesias, the patient may be able to suppress them, although only for a short time. Isolated tics are common in childhood and usually disappear. Tourette syndrome is defined by the presence of multiple motor and vocal tics that may evolve over time; it is frequently associated with psychiatric disease, including obsessive compulsions, depression, self-harm or attention deficit disorder. Tics may also occur in Huntington and Wilson diseases, or after streptococcal infection.

Abnormal perception

The parietal lobes are involved in the higher processing and integration of primary sensory information. This takes place in areas referred to as 'association' cortex, damage to which gives rise to sensory (including visual) inattention, disorders of spatial perception and disruption of spatially orientated behaviour, leading to apraxias. Apraxia is the inability to perform complex, organised activity in the presence of normal basic motor, sensory and cerebellar function (after weakness, numbness and ataxia have been excluded as causes). Examples of complex motor activities include dressing, using cutlery and geographical orientation. Other abnormalities that can result from damage to the association cortex involve difficulty reading (dyslexia) or writing (dysgraphia), or the inability to recognise familiar objects (agnosia). The results of damage to particular lobes of the brain are given in Box 27.2 above.

Altered balance and vertigo

Balance is a complicated dynamic process that requires ongoing modification of both axial and limb muscles to compensate for the effects of gravity and alterations in body position and load (and hence centre of gravity) in order to prevent a person from falling. This requires input from a variety of sensory modalities (visual, vestibular and proprioceptive), processing by the cerebellum and brainstem, and output via a number of descending pathways (e.g. vestibulospinal, rubrospinal and reticulospinal tracts).

Disorders of balance can therefore arise from any part of this process. Disordered input (loss of vision, vestibular disorders or lack of joint position sense), processing (damage to vestibular nuclei or cerebellum) or motor function (spinal cord lesions, leg weakness of any cause) can all impair balance. The patient may complain of different symptoms, depending on the location of the lesion. For example, loss of joint position sense or cerebellar function may result in a sensation of unsteadiness, while damage to the vestibular nuclei or labyrinth may result in an illusion of movement, such as vertigo (see below). A careful history is vital. Since vision can often compensate for lack of joint position sense, patients with peripheral neuropathies or dorsal column loss will often find their problem more noticeable in the dark.

Examination of such patients may yield physical signs that again depend on the site of the lesion. Sensory abnormalities may be manifest as altered visual acuities or visual fields, possibly with abnormalities on fundoscopy, altered eye movements (including nystagmus, impaired vestibular function or lack of joint position sense. Disturbance of cerebellar function may be manifest as nystagmus, dysarthria or ataxia, or difficulty with gait (unsteadiness or inability to perform tandem gait; see below). Leg weakness, if present, will be detectable on examination of the limbs.

Vertigo

Vertigo is defined as an abnormal perception of movement of the environment or self, and occurs because of conflicting visual, proprioceptive and vestibular information about a person's position in space. Vertigo commonly arises from imbalance of vestibular input and is within the experience of most people, since this is the 'dizziness' that occurs after someone has spun round vigorously and then stops. Bilateral labyrinthine dysfunction often causes some unsteadiness. Labyrinthine vertigo usually lasts days at a time, though it may recur, while vertigo arising from central (brainstem) disorders is often persistent and accompanied by other brainstem signs. Benign paroxysmal positional vertigo lasts a few seconds on head movement. A careful history will reveal the likely cause in most patients.

Abnormal gait

Many neurological disorders can affect gait. Observing patients as they walk into the consulting room can be very informative, although formal examination is also important. Neurogenic gait disorders need to be distinguished from those due to skeletal abnormalities, usually characterised by pain producing an antalgic gait, or limp. Gait alteration incompatible with any anatomical or physiological deficit may be due to functional disorders.

Pyramidal gait

Upper motor neuron lesions cause characteristic extension of the affected leg. The resultant tendency for the toes to strike the ground on walking requires the leg to swing outwards at the hip (circumduction). A shoe on the affected side worn down at the toes may provide evidence of this type of gait. In hemiplegia, the asymmetry between affected and normal sides is obvious on walking, but in paraparesis both lower limbs swing slowly from the hips in extension and are dragged stiffly over the ground – described as 'walking in mud'.

Foot drop

In normal walking, the heel is the first part of the foot to hit the ground. A lower motor neuron lesion affecting the leg will cause weakness of ankle dorsiflexion, resulting in a less controlled descent of the foot, which makes a slapping noise as it hits the ground. In severe cases, the foot will have to be lifted higher at the knee to allow room for the inadequately dorsiflexed foot to swing through, resulting in a high-stepping gait.

Myopathic gait

During walking, alternating transfer of the body's weight through each leg requires adequate hip abduction. In proximal muscle weakness, usually caused by muscle disease, the hips are not properly fixed by these muscles and trunk movements are exaggerated, producing a rolling or waddling gait.

Ataxic gait

An ataxic gait can result from lesions in the cerebellum, vestibular apparatus or peripheral nerves. Patients with lesions of the central portion of the cerebellum (the vermis) walk with a characteristic broad-based gait 'as if drunk' (cerebellar function is particularly sensitive to alcohol). Patients with acute vestibular disturbances walk similarly but the accompanying vertigo is characteristic. Inability to walk heel to toe may be the only sign of less severe cerebellar dysfunction.

Proprioceptive defects can also cause an ataxic gait. The impairment of joint position sense makes walking unreliable, especially in poor light. The feet tend to be placed on the ground with greater emphasis, presumably to enhance proprioceptive input, resulting in a 'stamping' gait.

Apraxic gait

In an apraxic gait, power, cerebellar function and proprioception are normal on examination of the legs. The patient may be able to carry out complex motor tasks (e.g. bicycling motion) while recumbent and yet cannot formulate the motor act of walking. In this higher cerebral dysfunction, the feet appear stuck to the floor and the patient cannot walk. Gait apraxia is a sign of diffuse bilateral hemisphere disease (such as normal pressure hydrocephalus) or diffuse frontal lobe disease.

Marche à petits pas

This gait is characterised by small, slow steps and marked instability. It differs from the festination found in Parkinson disease (see below), in that it lacks increasing pace and freezing. The usual cause is small-vessel cerebrovascular disease and there may be accompanying bilateral upper motor neuron signs.

Extrapyramidal gait

The rigidity and bradykinesia of basal ganglia dysfunction lead to a stooped posture and characteristic gait difficulties, with problems initiating walking and controlling the pace of the gait. Patients may become stuck while trying to start walking or when walking through doorways ('freezing'). The centre of gravity will be moved forwards to aid propulsion, which, with poor axial control, can lead to an accelerating pace of shuffling and difficulty stopping. This produces the festinant gait: initial stuttering steps that quickly increase in frequency while decreasing in length.

Abnormal speech and language

Speech disturbance may be isolated to disruption of sound output (dysarthria) or may involve language disturbance (dysphasia). Dysphonia (reduction in the sound/volume) is usually due to mechanical laryngeal disruption, whereas dysarthria is more typically neurological in origin. Dysphasia is always neurological and localises to the dominant cerebral hemisphere (usually left, regardless of handedness). Combinations of speech and swallowing problems are explained below.

Dysphonia

Dysphonia describes hoarse or whispered speech. The most common cause is laryngitis, but dysphonia can also result from a lesion of the 10th cranial nerve or disease of the vocal cords, including laryngeal dystonia. Parkinsonism may cause hypophonia with marked reduction in speech volume, often in association with dysarthria, making speech difficult to understand.

Dysarthria

Dysarthria is characterised by poorly articulated or slurred speech and can occur in association with lesions of the cerebellum, brainstem and lower cranial nerves, as well as in myasthenia or myopathic disease. Language function is not affected. The quality of the speech tends to differ, depending on the cause, but it can be very difficult to distinguish the different types clinically (Box 27.18). Dysarthria is discussed further in the section on bulbar symptoms below.

Dysphasia

Dysphasia (or aphasia) is a disorder of the language content of speech and writing (note we refer to speech below but written language is also involved). It can occur with lesions over a wide area of the dominant hemisphere (Fig. 27.23). Dysphasia may be categorised according to whether the speech output is fluent or non-fluent. Fluent aphasias, also called receptive aphasias, are impairments related mostly to the input or reception of language, with difficulties either in auditory verbal comprehension or in the repetition of words, phrases or sentences spoken by others. Speech is easy and fluent but there are difficulties related to the output of language as well, such as paraphasia (either substitution of similar-sounding non-words, or incorrect words) and neologisms (non-existent words).

Non-fluent aphasias, also called expressive aphasias, are difficulties in producing grammatically correct speech, but in most cases there is relatively good auditory verbal comprehension. Speech may appear jumbled in order, words may be incorrect or 'difficult to find' leading to hesitancy and circumlocution, or purely nonsense speech may occur. Examples include Broca aphasia (associated with pathologies in the inferior frontal region), transcortical motor aphasia and global aphasia.

'Pure' aphasias are selective impairments in reading, writing or the recognition of words. These disorders may be quite selective. For example, a person is able to read but not write, or is able to write but not read. Examples include pure alexia, agraphia and pure word deafness.

Dysphasia (a focal symptom) is frequently misinterpreted as disorientation (which is non-focal) and it is important always to consider dysphasia as an alternative explanation for the apparently 'confused' patient.

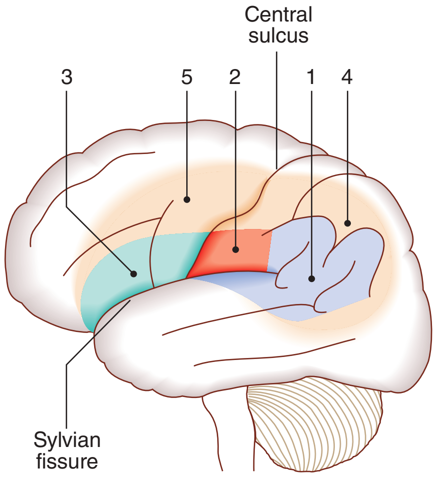


Fig. 27.23 Classification of cortical speech problems. (1) Wernicke aphasia: fluent dysphasia with poor comprehension and poor repetition. (2) Conduction aphasia: fluent aphasia with good comprehension and poor repetition. (3) Broca aphasia: non-fluent aphasia with good comprehension and poor repetition. (4) Transcortical sensory aphasia: fluent aphasia with poor comprehension and good repetition. (5) Transcortical motor aphasia: non-fluent aphasia with good comprehension and good repetition. Large lesions affecting all of regions 1–5 cause global aphasia.

27.18 Causes of dysarthria

Type	Site	Characteristics	Associated features
Myopathic	Muscles of speech	Indistinct, poor articulation	Weakness of face, tongue and neck
Myasthenic	Motor end plate	Indistinct with fatigue and dysphonia Fluctuating severity	Ptosis, diplopia, facial and neck weakness
Bulbar	Brainstem	Indistinct, slurred, often nasal	Dysphagia, diplopia, ataxia
'Scanning'	Cerebellum	Slurred, impaired timing and cadence, 'sing-song'	Ataxia of limbs and gait, tremor of head/limbs Nystagmus
Spastic ('pseudo-bulbar')	Pyramidal tracts	Indistinct, nasal tone, mumbling	Poor rapid tongue movements, increased reflexes and jaw jerk
Parkinsonian	Basal ganglia	Indistinct, rapid, stammering, quiet	Tremor, rigidity, slow shuffling gait
Dystonic	Basal ganglia	Strained, slow, high-pitched	Dystonia, athetosis

Dysphasia can be misheard/misspelt as dysphagia, and for this reason some prefer to use ‘aphasia’ to avoid confusion.

Disturbance of smell

Symptomatic olfactory loss is most commonly due to local causes (nasal obstruction) but may follow head injury. Hyposmia may predate motor symptoms in Parkinson disease by many years, although it is rarely noticed by the patient. Frontal lobe lesions are a rare cause. Positive olfactory symptoms may arise in Alzheimer disease or epilepsy.

Visual disturbance and ocular abnormalities

Disturbances of vision may be due to primary ocular disease or to disorders of the central connections and visual cortex. Visual symptoms are usually negative (loss of vision) but sometimes positive, most commonly in migraine. Eye movements may be disturbed, giving rise to double vision (diplopia) or blurred vision. Loss of vision is also discussed on page 1251.

Visual loss

Visual loss can occur as the result of lesions in any areas between the retina and the visual cortex. Patterns of visual field loss are explained by the anatomy of the visual pathways (see Fig. 27.7). Visual symptoms affecting one eye only are due to lesions anterior to the optic chiasm.

Transient visual loss is quite common and sudden-onset visual loss lasting less than 15 minutes is likely to have a vascular origin. It may be difficult to know whether the visual loss was monocular (carotid circulation) or binocular (vertebrobasilar circulation), and it is important to ask if the patient tried closing each eye in turn to see whether the symptom affected one eye or both. Visual field testing is an important part of the examination, either at the bedside or formally with perimetry. Field defects become more symmetrical (congruous), the closer the lesion comes to the visual cortex.

Migrainous visual symptoms are very common and, when associated with typical headache and other migraine features, rarely pose a diagnostic challenge. They may occur in isolation, however, making distinction from TIA difficult, but TIAs typically cause negative (blindness) symptoms, whereas migraine causes positive phenomena (see below). TIAs often last for a shorter time (a few minutes), compared to the 10- to 60-minute duration of migraine aura, and have an abrupt onset and end, unlike the gradual evolution of a migraine aura.

Positive visual phenomena

The most common cause is migraine; patients may describe silvery zigzag lines (fortification spectra) or flashing coloured lights (teichopsia), usually preceding the headache. Simple flashes of light (phosphenes) may indicate damage to the retina (e.g. detachment) or to the primary visual cortex. Formed visual hallucinations may be caused by drugs or may be due to epilepsy or ‘release phenomena’ in a blind visual field (Charles Bonnet syndrome).

Double vision

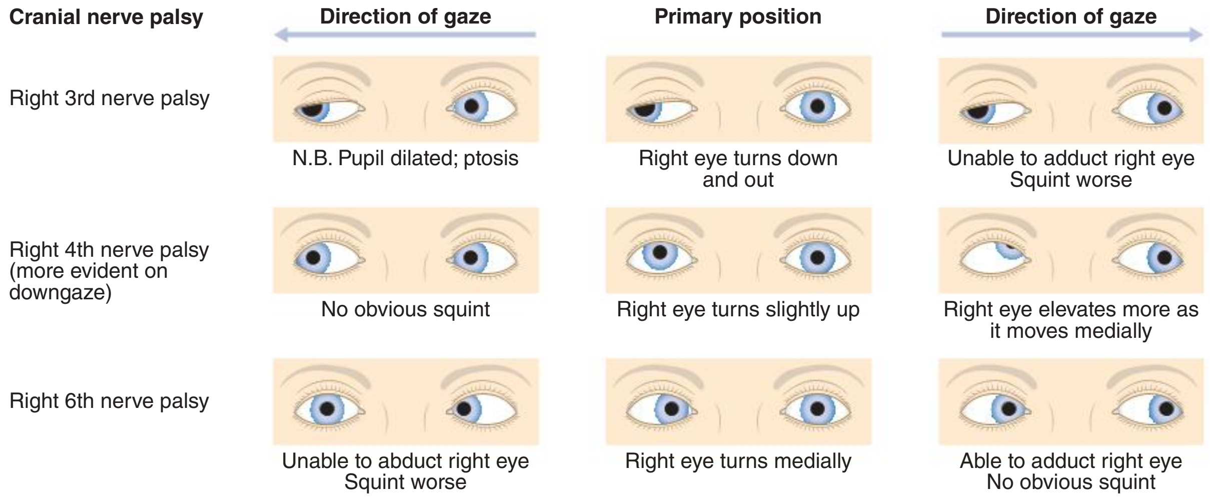
Diplopia arises from misalignment of the eyes, meaning that the image is not projected to the same points on the two retinas. At its most subtle it may be reported as blurred rather than double vision. Monocular diplopia indicates ocular disease, while binocular diplopia suggests a neurological cause. Closing either eye in turn will abort binocular diplopia. Once the presence of binocular diplopia is confirmed, it should be established whether the diplopia is maximal in any particular direction of gaze, whether the images are separated horizontally or vertically, and whether there are any associated symptoms or signs, such as ptosis or pupillary disturbance.

Binocular diplopia may result from central disorders or from disturbance of the ocular motor nerves, muscles or the neuromuscular junction (see Fig. 27.8). The pattern of double vision, along with any associated features, usually allows the clinician to infer which nerves/muscles are affected, while the mode of onset and other features (e.g. fatigability in myasthenia) provide further clues to the cause.

The causes of ocular motor nerve palsies are listed in Box 27.19. Examination findings are illustrated in Figure 27.24.

27.19 Common causes of damage to cranial nerves 3, 4 and 6

Site	Common pathology	Nerve(s) involved	Associated features
Brainstem	Infarction Haemorrhage Demyelination Intrinsic tumour	3 (mid-brain) 6 (ponto-medullary junction)	Contralateral pyramidal signs Ipsilateral lower motor neuron facial palsy Other brainstem/cerebellar signs
Intrameningeal	Meningitis (infective/malignant)	3, 4 and/or 6	Meningism, features of primary disease course
	Raised intracranial pressure	6 3 (uncal herniation)	Papilloedema Features of space-occupying lesion
	Aneurysms	3 (posterior communicating artery) 6 (basilar artery)	Pain (may result in isolated dilated pupil) Features of subarachnoid haemorrhage
	Cerebello-pontine angle tumour	6	8, 7, 5 nerve lesions (order of likelihood) Ipsilateral cerebellar signs
	Trauma	3, 4 and/or 6	Other features of trauma
Cavernous sinus	Infection/thrombosis Carotid artery aneurysm Caroticocavernous fistula	3, 4 and/or 6	May be 5th nerve involvement also Pupil may be fixed, mid-position (Sympathetic plexus on carotid may also be affected)
Superior orbital fissure	Tumour (e.g. sphenoid wing meningioma) Granuloma	3, 4 and/or 6	May be proptosis, chemosis
Orbit	Vascular (e.g. diabetes, vasculitis) Infections Tumour Granuloma Trauma	3, 4 and/or 6	Pain Pupil often spared in vascular 3rd nerve palsy



Cranial nerve palsy
Direction of gaze
Primary position
Direction of gaze
Right 3rd nerve palsy
N.B. Pupil dilated; ptosis
Right eye turns down and out
Unable to adduct right eye Squint worse
Right 4th nerve palsy (more evident on downgaze)
No obvious squint
Right eye turns slightly up
Right eye elevates more as it moves medially
Right 6th nerve palsy
Unable to abduct right eye Squint worse
Right eye turns medially
Able to adduct right eye No obvious squint

Fig. 27.24 Examination findings in 3rd, 4th and 6th nerve palsy. Diplopia tends to be more obvious on lateral gaze compared to primary position.

Nystagmus

Nystagmus describes a repetitive to-and-fro movement of the eyes. In central lesions, the slow drifts are the primary abnormal movement, each followed by fast (corrective) phases. Nystagmus occurs because the control systems of the eyes are defective, causing them to drift off target; corrections then become necessary to return fixation to the object of interest, causing nystagmus. The direction of the fast phase is usually designated as the direction of the nystagmus because it is easier to see. Nystagmus may be horizontal, vertical or torsional, and usually involves both eyes synchronously. It may be a physiological phenomenon in response to sustained vestibular stimulation or movement of the visual world (optokinetic nystagmus). There are many causes of pathological nystagmus, the most common sites of lesions being the vestibular system, brainstem and cerebellum.

The brainstem and the cerebellum are involved in maintaining eccentric positions of gaze. Lesions will therefore allow the eyes to drift back in towards primary position, producing nystagmus with fast component beats in the direction of gaze (gaze-evoked nystagmus). This is the most common type of 'central' nystagmus; it is most commonly bidirectional and not usually accompanied by vertigo. Other signs of brainstem dysfunction may be evident. Brainstem disease may also cause vertical nystagmus.

Unilateral cerebellar lesions may result in gaze-evoked nystagmus when looking in the direction of the lesion, where the fast phases are directed towards the side of the lesion. Cerebellar hemisphere lesions also cause 'ocular dysmetria', an overshoot of target-directed, fast eye movements (saccades) resembling 'past-pointing' in limbs.

In vestibular lesions, damage to one of the horizontal canals or its connections will allow the tonic output from the healthy contralateral side to cause the eyes to drift towards the side of the lesion. This elicits recurrent compensatory fast movements away from the side of the lesion, manifest as unidirectional horizontal nystagmus. Vertical and torsional components can be seen with damage to other parts of the vestibular apparatus. The nystagmus of peripheral labyrinthine lesions is accompanied by vertigo and usually by nausea, vomiting and unsteadiness, but as the CNS habituates, the nystagmus disappears (fatigues) quite quickly. Central vestibular nystagmus is more persistent.

Nystagmus also occurs as a consequence of drug toxicity and nutritional deficiency (e.g. thiamin). The severity is variable, and it may or may not result in visual degradation, though it may be associated with a sensation of movement of the visual world (oscillopsia). Nystagmus may occur as a congenital phenomenon, in which case both phases are equal and 'pendular', rather than having alternating fast and slow components.

Ptosis

Various disorders may cause drooping of the eyelids (ptosis) and these are listed in Box 27.20 and shown on Figure 27.25.

Abnormal pupillary responses

Abnormal pupillary responses may arise from lesions at several points between the retina and brainstem. Lesions of the oculomotor nerve, ciliary ganglion and sympathetic supply produce characteristic ipsilateral disorders of pupillary function. 'Afferent' defects result from damage to an optic nerve, impairing the direct response of a pupil to light, although leaving the consensual response from stimulation of the normal eye intact. Structural damage to the iris itself can also result in pupillary abnormalities. Causes are given in Box 27.21. An example is shown in Figure 27.26.

Papilloedema

There are several causes of swelling of the optic disc but the term 'papilloedema' is reserved for swelling secondary to raised intracranial pressure, when obstructed axoplasmic flow from retinal ganglion cells results in swollen nerve fibres, which in turn cause capillary and venous congestion, producing papilloedema. Lack of papilloedema never excludes raised intracranial pressure. Optic disc swelling and papilloedema are also discussed on page 1260.

Optic atrophy

See Chapter 28.

Hearing disturbance

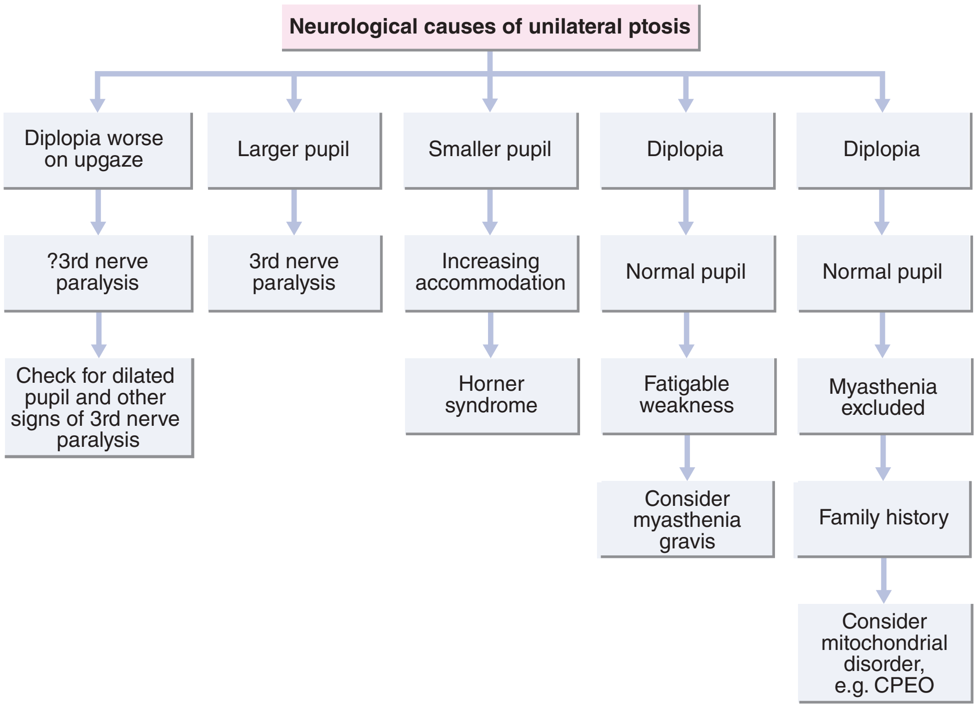
Each cochlear organ has bilateral cortical representation, so unilateral hearing loss is a result of peripheral organ damage. Bilateral hearing dysfunction is usual and is most commonly due to age-related degeneration or noise damage, although infection and drugs (particularly diuretics and aminoglycoside antibiotics) can be a primary cause. Prominent deafness may suggest a mitochondrial disorder (see Box 27.105).

Bulbar symptoms – dysphagia and dysarthria

Swallowing is a complex activity involving the coordinated action of lips, tongue, soft palate, pharynx and larynx, which are innervated by cranial nerves 7, 9, 10, 11 and 12. Structural causes of dysphagia are

27.20 Common causes of ptosis

Mechanism	Causes	Associated clinical features
3rd nerve palsy	Isolated palsy (see Box 27.19) Central/supranuclear lesion	Ptosis is usually complete Extraocular muscle palsy (eye 'down and out') Depending on site of lesion, other cranial nerve palsies (e.g. 4, 5 and 6) or contralateral upper motor neuron signs
Sympathetic lesion (Horner syndrome: see Fig. 27.24)	Central (hypothalamus/brainstem) Peripheral (lung apex, carotid artery pathology) Idiopathic	Ptosis is partial Lack of sweating on affected side Depending on site of lesion, brainstem signs, signs of apical lung/brachial plexus disease, or ipsilateral carotid artery stroke
Myopathic	Myasthenia gravis Dystrophia myotonica	Extraocular muscle palsies Usually bilateral More widespread muscle weakness, with fatigability in myasthenia Progressive external ophthalmoplegia Other characteristic features of individual causes
Other	Functional ptosis Pseudo-ptosis (e.g. blepharospasm) Local orbital/lid disease Age-related levator dehiscence	Resistance to eye opening Eyebrows depressed rather than raised May be local orbital abnormality



Neurological causes of unilateral ptosis

Fig. 27.25 Differential diagnosis of unilateral ptosis. (CPEO = chronic progressive external ophthalmoplegia)

considered on page 813. Neurological mechanisms are vulnerable to damage at different points, resulting in dysphagia that is usually accompanied by dysarthria. Tempo is again crucial: acute onset of dysphagia may occur as a result of brainstem stroke or a rapidly developing neuropathy, such as Guillain–Barré syndrome or diphtheria. Intermittent fatigable muscle weakness (including dysphagia) would suggest myasthenia gravis. Dysphagia developing over weeks or months may be seen in motor neuron disease, basal meningitis and inflammatory brainstem disease. More slowly developing dysphagia suggests a myopathy or possibly a brainstem or skull-base tumour.

Pathologies affecting lower cranial nerves (9, 10, 11 and 12) frequently manifest bilaterally, producing dysphagia and dysarthria. The term 'bulbar palsy' is used to describe lower motor neuron lesions, either within the medulla or outside the brainstem. The tongue may be wasted and fasciculating, and palatal movement is reduced.

Upper motor neuron innervation of swallowing is bilateral, so persistent dysphagia is unusual with a unilateral upper motor lesion (the exception being in the acute stages of, for example, a hemispheric stroke). Widespread lesions above the medulla will cause upper motor neuron bulbar paralysis, known as 'pseudobulbar palsy'. Here the tongue is small and contracted, and moves slowly; the jaw jerk is brisk, and there may be associated emotional variability. Causes of these are shown in Box 27.22.

Bladder, bowel and sexual disturbance

While isolated disturbances of bladder, bowel and sexual function are rarely the sole presenting features of neurological disease, they are common complications of many chronic disorders such as multiple sclerosis, stroke and dementia, and are frequently found post head injury.

27.21 Pupillary disorders

Disorder	Cause	Ophthalmological features	Associated features
3rd nerve palsy	See Box 27.20	Dilated pupil (especially with external compression) Extraocular muscle palsy (eye is typically 'down and out')	Other features of 3rd nerve palsy (see Box 27.20) Complete ptosis
Horner syndrome (see Fig. 27.24)	Lesion to sympathetic supply	Small pupil Partial ptosis	Ipsilateral failure of sweating (anhidrosis) Iris heterochromia (if congenital)
Holmes–Adie syndrome (tonic pupil)	Lesion of ciliary ganglion (usually idiopathic)	Dilated pupil Light–near dissociation (accommodate but do not react to light) Vermiform movement of iris during contraction Disturbance of accommodation	Generalised areflexia
Argyll Robertson pupil	Dorsal mid-brain lesion (syphilis or diabetes)	Small, irregular pupils Light–near dissociation	Other features of tabes dorsalis (Box 27.82)
Local pupillary damage	Trauma/inflammatory disease	Irregular pupils, often with adhesions to lens (synechiae) Variable degree of reactivity	Other features of trauma/underlying inflammatory disease (e.g. cataract, blindness etc.)
Relative afferent pupillary defect (Marcus Gunn pupil)	Damage to optic nerve	Pupils symmetrical – swinging torch test reveals dilatation in abnormal eye	Decreased visual acuity/colour vision Central scotoma Optic disc swelling or pallor

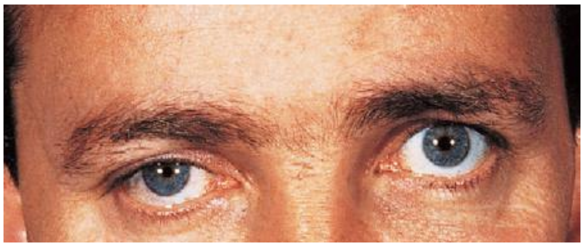

Fig. 27.26 Right-sided Horner syndrome due to paravertebral metastasis at T1. There is ipsilateral partial ptosis and a small pupil.

27.22 Causes of pseudobulbar and bulbar palsy

Type	Pseudobulbar	Bulbar
Genetic	–	Kennedy disease (X-linked bulbospinal neuronopathy)
Vascular	Bilateral hemisphere (lacunar) infarction	Medullary infarction (see Box 27.3)
Degenerative	Motor neuron disease	Motor neuron disease Syringobulbia
Inflammatory/ infective	Multiple sclerosis Cerebral vasculitis	Myasthenia Guillain–Barré syndrome Poliomyelitis Lyme disease Vasculitis
Neoplastic	High brainstem tumours	Brainstem glioma Malignant meningitis

Abnormalities in these functions considerably reduce quality of life for patients. Incontinence and its management are discussed elsewhere (pp. 608, 851 and 1347).

Bladder dysfunction

The anatomy and physiology involved in controlling bladder functions are discussed in Chapter 18, but it is worth emphasising the role of the pontine micturition centre, which is itself under higher control via inputs from the pre-frontal cortex, mid-brain and hypothalamus.

In the absence of conscious control (e.g. in coma or dementia), distension of the bladder to near capacity evokes reflex detrusor contraction (analogous to the muscle stretch reflex), and reciprocal changes in sympathetic activation and relaxation of the distal sphincter result in coordinated bladder emptying.

Damage to the lower motor neuron pathways (the pelvic and pudendal nerves) produces a flaccid bladder and sphincter with overflow incontinence, often accompanied by loss of pudendal sensation. Such damage may be due to disease of the conus medullaris or sacral nerve roots, either within the dura (as in inflammatory or carcinomatous meningitis) or as they pass through the sacrum (trauma or malignancy), or due to damage to the nerves themselves in the pelvis (infection, haematoma, trauma or malignancy).

Damage to the pons or spinal cord results in an 'upper motor neuron' pattern of bladder dysfunction due to uncontrolled over-activity of the parasympathetic supply. The bladder is small and highly sensitive to being stretched. This results in frequency, urgency and urge incontinence. Loss of the coordinating control of the pontine micturition centre will also result in the phenomenon of detrusor–sphincter dyssynergia, in which detrusor contraction and sphincter relaxation are not coordinated; the spastic bladder will often try to empty against a closed sphincter. This manifests as both urgency and an inability to pass urine, which is distressing and painful. The resultant incomplete bladder emptying predisposes to urinary infection, and the prolonged high intravesical pressure may result in obstructive uropathy and renal failure; post-micturition bladder ultrasound may confirm incomplete bladder emptying. More severe lesions of the spinal cord, as in spinal cord compression or trauma, can result in painless urinary retention as bladder sensation, normally carried in the lateral spinothalamic tracts, will be disrupted.

Damage to the frontal lobes gives rise to loss of awareness of bladder fullness and consequent incontinence. Coexisting cognitive impairment may result in inappropriate micturition. These features may be seen in hydrocephalus, frontal tumours, dementia and bifrontal subdural haematomas.

When a patient presents with bladder symptoms, it is important to localise the lesion on the basis of history and examination, remembering that most bladder problems are not neurological unless there are overt neurological signs. Clinical features and management are summarised in Box 27.23.

Rectal dysfunction

The rectum has an excitatory cholinergic input from the parasympathetic sacral outflow, and inhibitory sympathetic supply similar to the bladder. Continence depends largely on skeletal muscle contraction

27.23 Neurogenic bladder: clinical features and treatment

Type	Site of lesion	Result	Treatment
Atonic (lower motor neuron)	Sacral segments of cord (conus medullaris)	Loss of detrusor contraction	Intermittent self-catheterisation
	Sacral roots and nerves	Difficulty initiating micturition Bladder distension with overflow	In-dwelling catheterisation
Hypertonic (upper motor neuron)	Pyramidal tract in spinal cord or brainstem	Urgency with urge incontinence Bladder sphincter incoordination (dyssynergia)	Anticholinergics: Solifenacin Tolterodine Imipramine
		Incomplete bladder emptying	Intermittent self-catheterisation
Cortical	Post-central Pre-central Frontal	Loss of awareness of bladder fullness Difficulty initiating micturition Inappropriate micturition Loss of social control	Intermittent or in-dwelling catheterisation

in the puborectalis and pelvic floor muscles supplied by the pudendal nerves, as well as the internal and external anal sphincters. Damage to the autonomic components usually causes constipation (a common early symptom in Parkinson disease), but diabetic neuropathy can be associated with diarrhoea. Lesions affecting the conus medullaris, the somatic S2–4 roots and the pudendal nerves may cause faecal incontinence.

Erectile failure and ejaculatory failure

These related functions are under autonomic control via the pelvic nerves (parasympathetic, S2–4) and hypogastric nerves (sympathetic, L1–2). Descending influences from the cerebrum are important for erection but it can occur as a reflex phenomenon in response to genital stimulation. Erection is largely parasympathetic and may be impaired by a number of drugs, including anticholinergic, antihypertensive and antidepressant agents. Sympathetic activity is important for ejaculation and may be inhibited by α-adrenoceptor antagonists (α-blockers).

Personality change

While this is often due to psychiatric illness, neurological conditions that alter the function of the frontal lobes can cause personality change and mood disorder (see Box 27.2). Personality change due to a frontal lobe disorder may occur as the result of structural damage due to stroke, trauma, tumour or hydrocephalus. The nature of any change may help localise the lesion.

Patients with mesial frontal lesions become increasingly withdrawn, unresponsive and mute (abulic), often in association with urinary incontinence, gait apraxia and an increase in tone known as 'gegenhalten' or paratonia, in which the patient varies the resistance to movement in proportion to the force exerted by the examiner.

Patients with lesions of the dorsolateral pre-frontal cortex develop a dysexecutive syndrome, which involves difficulties with speech, motor planning and organisation. Those with orbitofrontal lesions of the frontal lobes, in contrast, become disinhibited, displaying grandiosity or irresponsible behaviour. Memory is substantially intact but frontal release signs may emerge, such as a grasp reflex, palmomental response or pout. Proximity to the olfactory bulb and tracts means that inferior frontal lobe tumours may be associated with anosmia.

Disturbance to the cortical areas responsible for speech or memory can result in changes that may be interpreted as changes in personality.

Sleep disturbance

Disturbances of sleep are common and are not usually due to neurological disease. Patients may complain of insomnia (difficulty sleeping), excessive daytime sleepiness, disturbed behaviour during night-time sleep, parasomnia (sleep walking and talking, or night terrors) or disturbing subjective experiences during sleep and/or its onset (nightmares, hypnagogic hallucinations, sleep paralysis). A careful history (from bed partner as well as patient) usually allows specific causes of sleep disturbance to be identified and these are discussed in more detail on page 1204.

Psychiatric disorders

Psychiatric disorders may cause or result from neurological problems. Care is needed in their identification, as effective management will help the underlying neurological illness.

Mood and sleep disturbance will exacerbate neurological symptoms, thus increasing disability. The best practitioners have the skill to carry the patient with them when describing the patterns of behaviour contributing to worsening symptoms.

Assessment to detect an underlying or exacerbating mood disorder is vital in all patients, ensuring that depression and anxiety are managed to minimise their secondary effects on neurological symptoms.

Headache syndromes

Acute management of headache is dealt with on page 222, but management of chronic, complex or refractory headaches may require specialist input. Headaches may be classified as primary or secondary, depending on the underlying cause (see Box 27.13). Secondary headache may be due to structural, infective, inflammatory or vascular conditions, discussed later in this chapter. Primary headache syndromes are described here.

Tension-type headache

This is the most common type of headache and is experienced to some degree by the majority of the population.

Pathophysiology

Tension-type headache is incompletely understood, and some consider that it is simply a milder version of migraine; certainly, the original notion that it is due primarily to muscle tension (hence the unsatisfactory name) has long since been dismissed. Anxiety about the headache itself may lead to continuation of symptoms, and patients may become convinced of a serious underlying condition.

Clinical features

The pain of tension headache is characterised as 'dull', 'tight' or like a 'pressure', and there may be a sensation of a band round the head or pressure at the vertex. It is of constant character and generalised, but often radiates forwards from the occipital region. It may be episodic or persistent, although the severity may vary, and there is no associated vomiting or photophobia. Tension-type headache is rarely disabling and patients appear well. The pain often progresses throughout the day. Tenderness may be present over the skull vault or in the occiput but is easily distinguished from the triggered pains of trigeminal neuralgia and the exquisite tenderness of temporal arteritis. Analgesics may be taken with chronic regularity, despite little effect, and may perpetuate the symptoms (see 'Medication overuse headache' below).

Management

Most benefit is derived from a careful assessment, followed by discussion of likely precipitants and reassurance that the prognosis is good. The concept of medication overuse headache needs careful explanation. An important therapeutic step is to allow patients to realise that their problem has been taken seriously and rigorously assessed. Physiotherapy (with muscle relaxation and stress management) may help and low-dose amitriptyline can provide benefit. Investigation is rarely required. The reassurance value of brain imaging needs careful assessment: the pick-up rate of structural abnormalities is exceedingly low, and significantly outweighed by the likelihood of identifying an incidental and irrelevant finding (e.g. an arachnoid cyst, Chiari I malformation or vascular abnormality). The value of such 'reassurance' is usually over-estimated by doctors and patients alike.

Migraine

Migraine usually appears before middle age, or occasionally in later life; it affects about 20% of females and 6% of males at some point in life. Migraine is usually readily identifiable from the history, although unusual variants can cause uncertainty.

Pathophysiology

The cause of migraine is unknown but there is increasing evidence that the aura (see below) is due to dysfunction of ion channels causing a spreading front of cortical depolarisation (excitation) followed by hyperpolarisation (depression of activity). This process (the 'spreading depression of Leão') spreads over the cortex at a rate of about 3 mm/min, corresponding to the aura's symptomatic spread. The headache phase is associated with vasodilatation of extracranial vessels and may be relayed by hypothalamic activity. Activation of the trigeminovascular system is probably important. A genetic contribution is implied by the frequently positive family history, and similar phenomena occurring in disorders such as CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy) or mitochondrial disease (p. 1241). The female preponderance and the frequency of migraine attacks at certain points in the menstrual cycle also suggest hormonal influences. Oestrogen-containing oral contraception sometimes exacerbates migraine and increases the very small risk of stroke in patients who suffer from migraine with aura. Doctors and patients often over-estimate the role of dietary precipitants such as cheese, chocolate or red wine. When psychological factors contribute, the migraine attack often occurs after a period of stress, being more likely on Friday evening at the end of the working week or at the beginning of a holiday.

Clinical features

Some patients report a prodrome of malaise, irritability or behavioural change for some hours or days. Around 20% of patients experience an aura and are said to have migraine with aura (previously known as classical migraine). The aura may manifest as almost any neurological symptom but is most often visual, consisting of fortification spectra, which are usually positive phenomena such as shimmering, silvery zigzag lines marching across the visual fields for up to 40 minutes, sometimes leaving a trail of temporary visual field loss (scotoma). Sensory symptoms characteristically spreading over 20–30 minutes, from one part of the body to another, are more common than motor ones, and language function can be affected, leading to similarities with TIA/stroke. Isolated aura may occur (i.e. the neurological symptoms are not followed by headache).

The 80% of patients with characteristic headache but no 'aura' are said to have migraine without aura (previously called 'common' migraine).

Migraine headache is usually severe and throbbing, with photophobia, phonophobia and vomiting lasting from 4 to 72 hours. Movement makes the pain worse and patients prefer to lie in a quiet, dark room.

In a small number of patients, the aura may persist, leaving more permanent neurological disturbance. This persistent migrainous aura may occur with or without evidence of brain infarction.

Management

Avoidance of identified triggers or exacerbating factors (such as the combined contraceptive pill) may prevent attacks. Treatment of an acute attack consists of simple analgesia with aspirin, paracetamol or non-steroidal anti-inflammatory agents. Nausea may require an antiemetic such as metoclopramide or domperidone. Severe attacks can be aborted by one of the 'triptans' (e.g. sumatriptan), which are potent 5-hydroxytryptamine (5-HT, serotonin) agonists. These can be administered via the oral, subcutaneous or nasal route. Caution is needed with ergotamine preparations because they may lead to dependence. Overuse of any analgesia, including triptans, may contribute to medication overuse headache.

If attacks are frequent (more than two per month), prophylaxis should be considered. Many drugs can be chosen but the most frequently used are vasoactive drugs (β-adrenoceptor antagonists (β-blockers), candesartan, lisinopril), antidepressants (amitriptyline, dosulepin) and antiseizure medications (topiramate, although alternative effective prophylactic drugs should be considered in women because of the high teratogenicity). Consideration needs to be given to the teratogenicity of antiseizure medications in women. Monoclonal antibodies to calcitonin gene–related peptide (CGRP) receptor are available as once monthly subcutaneous injections for refractory migraine, and CGRP antagonists in tablet form (known collectively as gepants), some of which can be used for acute migraine if triptans are contraindicated or not tolerated. Women with aura should avoid oestrogen treatment for either oral contraception or hormone replacement, although the increased risk of ischaemic stroke is minimal.

Medication overuse headache

With increasing availability of over-the-counter medication, headache syndromes perpetuated by analgesia intake are becoming much more common. Medication overuse headache (MOH) can complicate any headache syndrome but is especially common with migraine and chronic tension-type headache. The most frequent culprits are compound analgesics (particularly codeine and other opiate-containing preparations) and triptans, and MOH is usually associated with use on more than 10–15 days per month.

Management is by withdrawal of the responsible analgesics. Patients should be warned that the initial effect will be to exacerbate the headache, and migraine prophylactics may be helpful in reducing the rebound headaches. Relapse rates are high, and patients often need help and support in withdrawing from analgesia; a careful explanation of this paradoxical concept is vital.

Cluster headache

Cluster headaches (also known as migrainous neuralgia) are much less common than migraine. Unusually for headache syndromes, there is a significant male predominance and onset is usually in the third decade.

Pathophysiology

The cause is unknown but this type of headache differs from migraine in many ways, suggesting a different pathophysiological basis. Although uncommon, it is the most common of the trigeminal autonomic cephalalgia syndromes. Functional imaging studies have suggested abnormal hypothalamic activity. Patients are more often smokers with a higher than average alcohol consumption.

Clinical features

Cluster headache is strikingly periodic, featuring runs of identical headaches beginning at the same time for weeks at a stretch (the 'cluster'). Patients may experience either one or several attacks within a 24-hour period, and typically are awoken from sleep by symptoms ('alarm clock headache'). Cluster headache causes severe, unilateral periorbital pain with autonomic features, such as ipsilateral tearing, nasal congestion and conjunctival injection (occasionally with the other features of a Horner syndrome). The pain, though severe, is characteristically brief (30–90 minutes). In contrast to the behaviour of those with migraine, patients are highly agitated during the headache phase. The cluster period is typically a few weeks, followed by remission for months to years, but a small proportion do not experience remission.

Management

Acute attacks can usually be halted by subcutaneous injections of sumatriptan or inhalation of 100% oxygen. The brevity of the attack probably prevents other migraine therapies from being effective. Migraine prophylaxis is often ineffective too but attacks can be prevented in some patients by verapamil or short courses of oral glucocorticoids. If these are ineffective, at least one of the monoclonal antibody CGRP inhibitors used for migraine, galcanezumab, can be used. Patients with severe debilitating clusters can be helped with lithium therapy, although this requires monitoring.

Trigeminal neuralgia

This is characterised by unilateral lancinating facial pain, most commonly involving the second and/or third divisions of the trigeminal nerve territory, usually in patients over the age of 50 years.

Pathophysiology

For most, trigeminal neuralgia remains an idiopathic condition but there is a suggestion that it may be due to an irritative lesion involving the trigeminal root zone, in some cases an aberrant loop of artery. Other compressive lesions, usually benign, are occasionally found. Trigeminal neuralgia associated with multiple sclerosis may result from a plaque of demyelination in the brainstem.

Clinical features

The pain is repetitive, severe and very brief (seconds or less). It may be triggered by touch, a cold wind or eating. Physical signs are usually absent, although the spasms may make the patient wince and sit silently (tic douloureux). There is a tendency for the condition to remit and relapse over many years. Rarely, there may be combined features of trigeminal neuralgia and cluster headache ('cluster–tic').

Management

The pain often responds to carbamazepine. It is wise to start with a low dose and increase gradually, according to effect. In patients who cannot tolerate carbamazepine, oxcarbazepine, gabapentin, pregabalin, baclofen, lamotrigine, phenytoin or glucocorticoids may be effective alternatives, but if medication is ineffective or poorly tolerated, surgical treatment should be considered. Decompression of the vascular loop encroaching on the trigeminal root is often performed and may lead to pain relief in some cases. A range of radiosurgery or percutaneous ablative surgical techniques can be used for refractory trigeminal neuralgia.

Headaches associated with specific activities

These usually affect men in their thirties and forties. Patients develop a sudden, severe headache with exertion, including sexual activity. There is usually no vomiting or neck stiffness, and the headache lasts less than 10–15 minutes, though a less severe dullness may persist for some hours. Subarachnoid haemorrhage needs to be excluded by CT and/or CSF examination (see Fig. 27.37) after a first event. The pathogenesis of these headaches is unknown. Although frightening, attacks are usually brief and patients may need only reassurance and simple analgesia for the residual headache. The syndrome may recur, and prevention may be necessary with propranolol or indometacin.

Other headache syndromes

A number of rare headache syndromes produce pains about the eye similar to cluster headaches (Box 27.24). These include chronic paroxysmal hemicrania and SUNCT (short-lasting unilateral neuralgiform headaches with conjunctival injection and tearing). The recognition of these syndromes is useful because they often respond to specific treatments such as indometacin.

27.24 Paroxysmal headaches

Type	Character of pain	Duration	Location	Comment
Ice pick	Stabbing	Very brief (split-second)	Variable, usually temporoparietal	Benign, more common in migraine
Ice cream	Sharp, severe	30–120 secs	Bitemporal/occipital	Obvious trigger by cold stimuli
Exertional/sexual activity	Bursting, thunderclap	Severe for mins, then less severe for hours	Generalised	Subarachnoid haemorrhage needs to be excluded
Cough	Bursting	Secs to mins	Occipital or generalised	Intracranial pathology needs to be excluded (especially craniocervical junction)
Cluster headache (migrainous neuralgia)	Severe unilateral, with ptosis, tearing, conjunctival injection, unilateral nasal congestion	30–90 mins 1–3 times per day	Periorbital	Usually in men, occurring in clusters over weeks/months
Chronic paroxysmal hemicrania	Severe unilateral with cluster headache-like autonomic features (see above)	5–20 mins, frequently through day	Periorbital/temporal	Usually in women, responds to indometacin
SUNCT*	Severe, sharp, triggered by touch or neck movements	15–120 secs, repetitive through day	Periorbital	May respond to carbamazepine

***S*hort-lasting, *u*nilateral, *n*euralgiform headache with *c*onjunctival injection, *t*earing, rhinorrhoea and forehead sweating.

Functional neurological disorder

Many patients present with functional symptoms and some may have a functional neurological disorder (FND). FND (also known as functional neurological symptom disorder, dissociative neurological symptom disorder, or in the past conversion disorder) is a disorder at the interface of neurology and psychiatry, reflecting function or dysfunction in the shared organ, the brain. The symptoms are involuntary and cause considerable disability. Core to the assessment and management of most patients is a diagnosis made on positive grounds, communicated to patients in a manner that contributes constructively to management.

Functional symptoms are not consistent with any other recognised neurological disease or disorder. The diagnosis depends on demonstrating internal inconsistency. The inconsistency will depend on the specific functional symptom. Functional symptoms include functional weakness, sensory disturbance, pain, movement disorders, dissociative attacks (also called non-epileptic attacks), visual symptoms, speech and cognitive symptoms. Examples of internal inconsistency include: weakness of hip extension when the patient tries to extend the hip, which is overcome when the opposite hip is flexed against resistance (Hoover sign); marked weakness of the legs on examination in a patient able to stand and walk; a detailed description of specific events of memory loss; and expressive dysphasia with retained written language. Other findings may include: non-anatomical sensory loss, abnormal movements that are distractable, and dissociative non-epileptic seizures occurring in the absence of concomitant EEG abnormality. Tiredness, poor concentration and sleep disturbance are also common.

Many but not all patients with FND have predisposing and perpetuating factors (Box 27.25) that may include anxiety, depression, post-traumatic stress disorder, a history of abuse or aversive events. There may be a precipitating event, which may at times appear minor in comparison to the range and severity of the patient's symptoms.

The approach to the patient with FND or functional symptoms should ideally include:

- a detailed history exploring all symptoms
- examination looking for positive findings, e.g. Hoover sign
- review of past medical records, which often contain functional symptoms in other organ systems, e.g. irritable bowel syndrome, globus, non-cardiac chest pain
- rapid investigation to exclude a structural cause
- and a clear, constructive explanation of the diagnosis based on positive findings rather than the rather unhelpful 'medically unexplained symptom' approach of the past.

There are several useful websites that provide patients with additional information and advice (p. 1243). For many patients, understanding their symptoms and the condition will be sufficient; others may require additional multidisciplinary support and treatment from a range of professionals including: physiotherapy, occupational and speech therapy, neurology and neuropsychiatry/psychiatry. Treatment may include neurophysiotherapy, use of antidepressant medication (although not all patients are depressed) and cognitive behavioural therapy. The diagnosis should not be made simply because the patient's presentation is unusual. A diagnosis of FND should be based on an appropriate history, examination and normal relevant findings on investigation. It is worth noting that FND can coexist with other pathologies. It is not uncommon to see stroke patients with superadded elements of FND. Neurodegenerative conditions, particularly atypical parkinsonian syndromes such as multiple system atrophy and Lewy body dementia, can present initially with functional neurological features. Functional neurological episodes may even be triggered by sudden events such as stroke. This emphasises the importance of careful clinical assessment and, when indicated, reassessment.

Factitious disorders and malingering are not the same as FND. In the absence of clear objective evidence, e.g. witnessing a patient tampering with tests, diagnosis of these disorders should best be left to psychiatrists.

i 27.25 Clinical features suggestive of functional disorder

- Inconsistent examination findings (e.g. Hoover sign)
- Situational provocation of events (e.g. in medical settings)
- Associated mental health disorders:
  - Anxiety
  - Depression
- Lack of anatomical coherence to neurological symptoms
- Florid or bizarre descriptions of individual symptoms
- History of multiple other systemic symptoms inadequately explained by disease (asthma/breathlessness, fatigue, pain, gastrointestinal symptoms)

Stroke

A stroke is a sudden onset focal cerebral dysfunction due to vascular disease of the brain (Fig. 27.27). Stroke is the third most common cause of disability in the world after ischaemic heart disease and congenital disorders. Stroke is a common medical emergency. In the UK about 150 per 100 000 people have a stroke each year. It is commoner with increasing age, poverty and vascular risk factors (Box 27.26). In Europe, most strokes (about 80%) are caused by cerebral ischaemia and fewer are due to haemorrhage, although there are probably a similar number of deaths due to ischaemic and haemorrhagic stroke worldwide. Subarachnoid haemorrhage (SAH) and cerebral venous thrombosis (CVT) are discussed later in this chapter. Vascular dementia is described on page 1293.

Pathophysiology

Cerebral infarction

Cerebral infarction is usually due to atherothromboembolism. The source of embolism can be the heart, particularly when there is atrial fibrillation (AF), or the rupture of large artery atherosclerosis and subsequent thromboembolism from carotid arteries, vertebral arteries and aortic arch. Intracranial atheroma can lead to in situ thrombosis. Occlusion of the small perforating lenticulostriate arteries in patients with sporadic or genetic small vessel diseases leads to 'lacunar' infarctions. Spontaneous cervical artery dissection is an important mechanism in younger people. Infarction can also be the result of low arterial flow, for example severe hypotension (sometimes intraoperative), vessel inflammation in children or adults with vasculitis, or failure in energy production in mitochondrial disease.

After the occlusion of a cerebral artery, the supply of oxygen, glucose and other nutrients to tissue falls, and neuronal functions begin to fail. If there are adequate collateral vessels, these may dilate and restore normal blood flow, or maintain a reduced blood flow that keeps tissue alive but not active. Cerebral tissue begins to die if there are inadequate collateral vessels, or the vessel is not re-opened by endogenous thrombolysis, thrombolytic medication or thrombectomy. The process of cell death leads to oedema of dying tissue, which can be life-threatening if it expands to increase intracranial pressure. Although reopening blood vessels is of overall benefit, restoration of blood supply can lead to a secondary injury, which is most obvious clinically in haemorrhagic transformation of an infarct, which is not infrequent (~3%) after thrombolytic therapy.

Fig. 27.27 A classification of stroke.

27.26 Risk factors for stroke

Fixed risk factors

- Age
- Sex (male > female)
- Previous vascular event:
  - Myocardial infarction
  - Stroke
  - Peripheral vascular disease
- Genetic pathogenic variants, e.g.
  - Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL)
  - Sickle-cell disorder

Risk factors

- Blood pressure
- Cigarette smoking
- High LDL cholesterol
- Diabetes mellitus
- Atrial fibrillation
- Chronic kidney disease
- Excessive alcohol intake
- Oestrogen-containing drugs:
  - Oral contraceptive pill
  - Hormone replacement therapy
- Polycythaemia
- Drugs, e.g. cocaine
- Heart disease:
  - Congestive cardiac failure
  - Infective endocarditis

If the patient survives the acute stages of infarction, healing begins with inflammation to clear dying tissue, recovery of some neurons and reorganisation of some cerebral function to other brain areas.

Intracerebral haemorrhage

The commonest cause of intracerebral haemorrhage is the rupture of small blood vessels. Small vessels can be damaged by hypertension, diabetes, amyloid deposition or genetic causes. Rupture of abnormalities of larger vessels, such as arteriovenous or cavernous malformations, and sometimes intracranial aneurysms (which usually presents as SAH) can also lead to intracerebral haemorrhage (Fig. 27.28). Haemorrhage leads to harm by direct pressure of the haematoma, which can continue to grow after presentation, mass effect from surrounding oedema, and inflammation due to degrading blood products. Haemorrhage recovers with the resorption of blood products, resolution of oedema, healing of neurons and cerebral re-organisation (Box 27.27).

Clinical features

Most strokes develop suddenly within a matter of minutes or hours, and are one of the differential diagnoses of patients with almost any acute focal neurological presentation.

Weakness

In severe stroke, involvement of large areas of the cortex or smaller areas of the deep white matter in the cerebrum or brainstem leads to

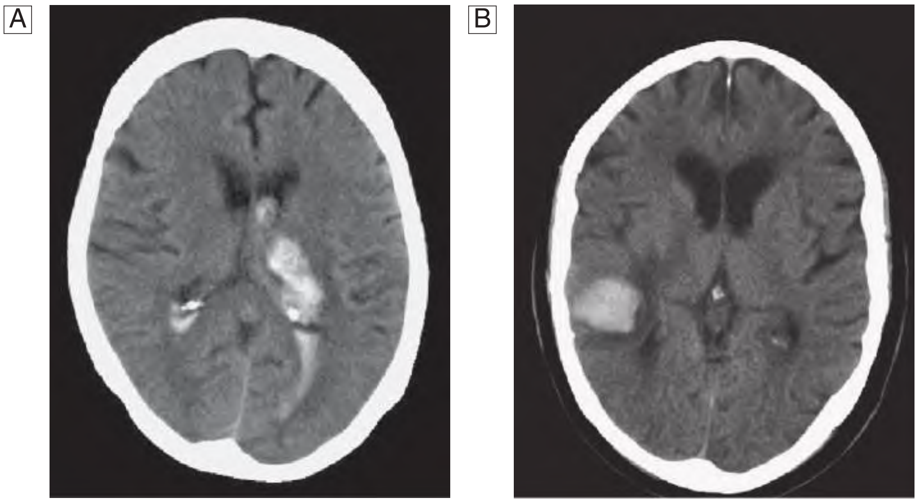

Fig. 27.28 **CT scans showing intracerebral haemorrhage.** **A** Basal ganglia haemorrhage with intraventricular extension. **B** Small cortical haemorrhage. *(A, B) Courtesy of Prof. A. Farrell and Prof. J. Wardlaw.*

27.27 Risk factors and causes of intracerebral haemorrhage

Disease	Risk factors
Small-vessel disease with disruption of vessel wall	Age Hypertension
Amyloid angiopathy	Familial (rare) Age
Impaired blood clotting	Anticoagulant therapy Thrombocytopenia Thrombolytic therapy Intracranial venous thrombosis
Vascular anomaly	Arteriovenous malformation Cavernous haemangioma Aneurysms
Substance misuse	Alcohol Amphetamines Cocaine

a hemiparesis (see Fig. 27.20). Other patterns of weakness include: face only (usually an upper motor neuron pattern affecting the lower face only); face and arm; leg only (anterior cerebral artery involvement); hand only (often a clumsiness); or a quadriparesis (with brainstem stroke).

Speech disturbance

Stroke can lead to a number of speech abnormalities. Cortical strokes (usually dominant frontal or parietal lobe) can cause dysphasia, with difficulties understanding speech (a receptive dysphasia) or difficulties producing grammatically correct speech (an expressive dysphasia). Stroke in the cortex, deep white matter, cerebellum or brainstem can lead to slurred speech (dysarthria). More rarely, isolated difficulties with reading (alexia) or writing (agraphia) occur, but they are more usually associated with other symptoms (see Box 27.2).

Visual deficit

Occlusion of the ophthalmic artery by thrombus leads to sudden blindness in one eye. If the blindness is transient, this is called 'transient monocular blindness' or 'amaurosis fugax'. These symptoms should lead to a similar search for risk factors and cause as stroke symptoms.

Stroke affecting the occipital lobe or optic tracts or radiation leads to a contralateral hemianopia or, in smaller lesions, a partial field defect (p. 1176).

Visuo-spatial dysfunction

Damage to the non-dominant cortex often results in contralateral visuo-spatial dysfunction, e.g. sensory or visual neglect and apraxia (inability to perform complex tasks despite normal motor, sensory and cerebellar function). Confusion or dysphasia after stroke are sometimes misdiagnosed as delirium.

Ataxia

Stroke causing damage to the cerebellum and its connections can present with an acute ataxia, and there may be associated brainstem features such as diplopia and vertigo. The differential diagnosis includes vestibular disorders.

Headache

Sudden severe headache is the cardinal symptom of SAH but also occurs in intracerebral haemorrhage. Although headache is common in acute ischaemic stroke, it is rarely a dominant feature. Headache also occurs in cerebral venous thrombosis and in giant cell arteritis. Migraine is a weak risk factor for stroke, and sometimes a stroke can precipitate a migraine attack.

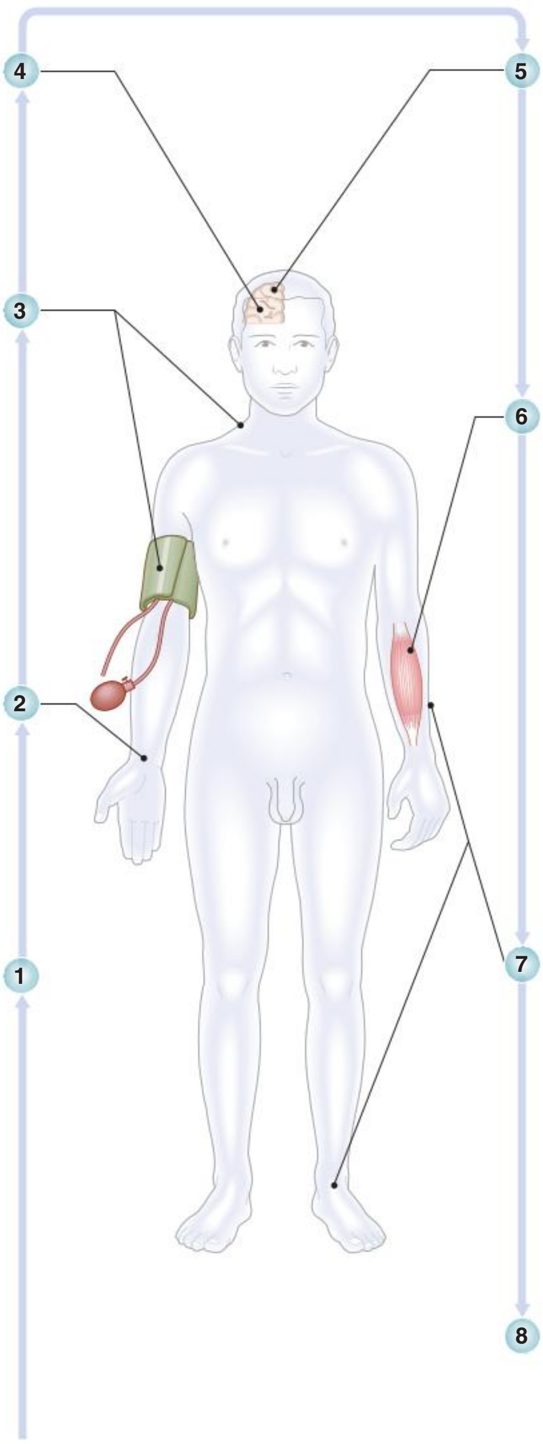
Seizure

Epileptic seizures are unusual in acute ischaemic stroke. Focal onset seizures can occur during stroke recovery, or during acute intracerebral haemorrhage or acute cerebral venous thrombosis (particularly of the cortical veins).

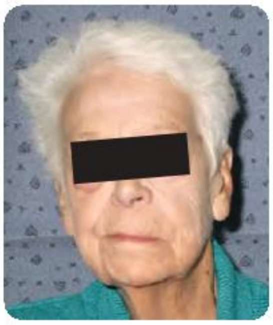
Coma

If a stroke patient presents with coma, it is usually due to a large intracerebral haemorrhage or brainstem stroke. Cortical ischaemic stroke patients can become comatose if they develop space-occupying cerebral oedema or develop complications of stroke such as pneumonia (see Box 10.31).

Examination



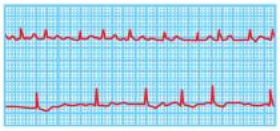
1 General appearance
Conscious level
Gaze deviation
Facial symmetry



[redacted]

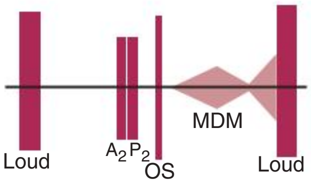
Left upper motor neuron pattern of facial weakness

2 Pulse
Rate and rhythm



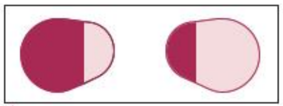
Atrial fibrillation

3 Blood pressure, carotid bruits and cardiac auscultation



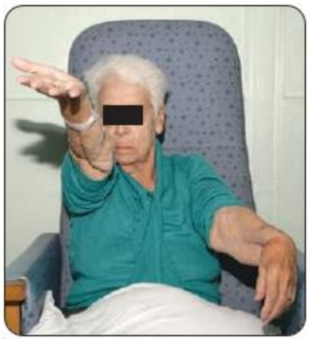
4 Higher cerebral function
Dysphasia or dysarthria
Attention and neglect
Abbreviated mental test

5 Cranial nerve function
Swallow
Horner syndrome
Internuclear ophthalmoplegia
Cranial nerve palsy, e.g. 3rd, 6th, 7th or 12th
Visual field loss



Visual field defect – left homonymous hemianopia

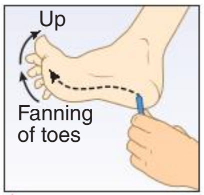
6 Motor system
Tone
Strength, including pronator drift
Co-ordination
Tendon reflexes
Plantar reflexes



[redacted]

Left pronator drift

7 Sensory system
Touch sensation
Cortical sensory function: sensory inattention or neglect
Joint position sense



Extensor plantar reflex

8 Gait
Sitting balance
Standing balance
Ataxic gait pattern
Hemiparetic gait pattern

Rapid clinical assessment of suspected stroke is performed using the National Institutes of Health Stroke Scale (NIHSS; Box 27.28). Blood sugar, blood pressure and swallow should be checked at the bedside. General examination should be delayed until after acute stroke treatments, like thrombolysis, have been given to eligible patients. Examination should pay attention to potential causes and any complications of the stroke (Box 27.29).

Differential diagnosis of stroke and transient ischaemic attacks

Both acute stroke and transient ischaemic attack (TIA) are characterised by a rapid-onset, focal deficit of brain function. Symptoms can be transient (TIA) or persistent (stroke). The symptoms of a typical stroke progress over minutes, affect an identifiable area of brain and are 'negative'

27.28 Rapid clinical assessment of suspected stroke

Exclusion of hypoglycaemia

- Bedside blood glucose testing

Measure blood pressure

- Significant hypertension may require treatment (e.g. in acute intracerebral haemorrhage, or if thrombolysis is being considered)

National Institutes of Health Stroke Scale (NIHSS)

A formalised neurological examination and a measure of stroke severity which can be useful for organising acute stroke assessment, monitoring and communicating stroke severity.

1 A Level of consciousness	
Alert; keenly responsive	0
Arouses to minor stimulation	+1
Arouses to pain	+2
Abnormal postures or unresponsive	+3
1B Ask month and age	
Both questions right	0
One question right or dysarthric or intubated	+1
No questions right or aphasic	+2
1 C Ask to 'close eyes' and 'squeeze hands'	
Performs both tasks	0
Performs one task	+1
Performs no tasks	+2
2 Horizontal extraocular movements	
Normal	0
Partial gaze palsy: can be overcome or corrects	+1
Complete gaze palsy: cannot be overcome	+2
3 Visual fields	
No visual loss	0
Partial hemianopia	+1
Complete hemianopia	+2
Bilateral blindness or hemianopia	+3
4 Facial palsy	
Normal symmetry	0
Minor paralysis (flat nasolabial fold)	+1
Partial paralysis (lower face only)	+2
Unilateral or bilateral complete paralysis	+3
5A Left arm motor drift (ask patient to hold out arm for 10 seconds while you count aloud)	
No drift for 10 seconds	0
Drift, but doesn't hit bed	+1
Drift and hits bed, or some effort against gravity	+2
No effort against gravity	+3
No movement	+4
5B Right arm motor drift (perform and score following instructions for left arm)	
6A Left leg motor drift (ask patient to raise leg for 5 seconds while you count aloud)	
No drift for 5 seconds	0
Drift, but doesn't hit bed	+1
Drift and hits bed, or some effort against gravity	+2
No effort against gravity	+3
No movement	+4
6B Right leg motor drift (perform and score following instructions for left leg)	
7 Limb ataxia (finger–nose–finger and heel–shin testing, all four limbs)	
No ataxia or doesn't understand or paralysed	0
Ataxia in one limb	+1
Ataxia in two limbs	+2
8 Sensation	
Normal, no sensory loss	0
Mild–moderate sensory loss	+1
Complete sensory loss or unresponsive	+2
9 Language (check comprehension 'lift your arms', 'close your eyes'. Ask the patient to name people or objects, e.g. 'nurse', 'pen', 'watch', to check for nominal dysphasia)	
Normal, no dysphasia	0
Mild–moderate dysphasia but no major limitation	+1
Severe dysphasia, e.g. meaning of speech is unclear	+2
Global aphasia or mute or coma	+3
10 Dysarthria (check articulation, e.g. repeat 'tip-top', or 'fifty-fifty')	
Normal or intubated and unable to test	0
Mild–moderate, e.g. slurring but understandable	+1
Severe, unintelligible or mute	+2
11 Inattention (test sensation and visual fields on both sides simultaneously. The affected side will not be felt or seen)	
Inattention to one modality (sense or vision)	+1
Inattention to both modalities or severe neglect (e.g. doesn't recognise own hand)	+2

Score (0 to 42): 0 to 5 mild, 5 to 15 moderate, more than 16 severe

Tips: Score what you see, score the first response (not the best response) and don't coach the patient. Check if the patient can sit up or stand without support. The NIHSS does not measure well the severity of posterior circulation and non-dominant hemisphere stroke syndromes.

27.29 General examination

Skin

- Xanthelasma
- Rash (e.g. vasculitic, splinter haemorrhages)
- Colour change (limb ischaemia, deep vein thrombosis)
- Pressure sores or early pressure injury

Eyes

- Diabetic retinopathy
- Hypertensive retinopathy
- Cholesterol emboli
- Papilloedema (unexpected in stroke)
- Subhyaloid haemorrhages (after subarachnoid haemorrhage)

Cardiovascular system

- Atrial fibrillation
- Blood pressure (high or low)
- Carotid bruit
- Cardiac murmurs (source of embolism, e.g. endocarditis)
- Peripheral pulses and bruits (generalised arteriopathy)

Respiratory system

- Signs of pulmonary oedema or infection
- Oxygen saturation

Abdomen

- Palpable bladder (urinary retention)
- Organomegaly

Locomotor system

- Injuries sustained during collapse (e.g. hip fracture)
- Comorbidities that influence recovery (e.g. osteoarthritis)

27.30 Differential diagnosis of stroke and transient ischaemic attack

- Seizure, particularly focal
- Syncope if history is unclear
- Sepsis presenting with delirium
- Migraine with aura
- Brain tumours
- Functional neurological symptoms
- Neuropathies
- Vertigo due to labyrinthopathy
- Multiple sclerosis
- Subdural haematoma
- Demyelination

27.31 Characteristic features of stroke and non-stroke syndromes ('stroke mimics')

Feature	Stroke	Non-stroke
Symptom onset	Sudden (minutes)	Often slower onset
Symptom progression	Rapidly reaches maximum severity	Often gradual onset
Symptom type	Negative (e.g. weakness)	Positive (e.g. abnormal movements)
Pattern of deficit	Hemispheric pattern	May be non-specific with delirium, memory loss, balance disturbance
Loss of consciousness	Uncommon	More common

(i.e. loss of function) (Box 27.30). If symptoms progress over hours or days, or if significant 'positive' features are present (e.g. spreading paraesthesiae, abnormal movements), other diagnoses are more likely (see Box 27.30). Persistent or transient symptoms that cannot be localised to one brain area, e.g. syncope, amnesia, delirium and dizziness, are more likely to have causes other than TIA or stroke (see Fig. 10.4 and Box 27.31). It is important to remember that anxiety is common in people presenting with stroke or TIA, but also that people with functional neurological disorders can present with acute onset weakness or collapse.

Stroke syndromes

The clinical syndrome of an ischaemic stroke depends on the arterial territory involved and the size of the lesion (see Fig. 27.27). These will both have a bearing on management, such as suitability for carotid endarterectomy. The presence of a unilateral motor deficit, a higher cerebral function deficit such as aphasia or neglect, or a visual field defect usually places the lesion in the cerebral hemisphere. Ataxia, diplopia, vertigo or bilateral weakness usually indicates a lesion in the brainstem or cerebellum. Different combinations of these deficits define several ischaemic stroke syndromes (Fig. 27.29), which reflect the site and size of the lesion and may provide clues to the underlying arterial occlusion.

Reduced conscious level usually indicates a large-volume lesion in the cerebral hemisphere but may result from a lesion in the brainstem or complications such as obstructive hydrocephalus, hypoxia or severe systemic infection (usually pneumonia). The combination of severe headache and vomiting at the onset of the focal deficit is suggestive of intracerebral haemorrhage, although headache is also a feature of giant cell arteritis and arterial dissection.

The definitions of strokes and TIA are:

- *Transient ischaemic attack (TIA):* a transient focal neurological dysfunction caused by brain or retinal ischaemia with no evidence of infarction, where symptoms resolve within 24 hours.
- *Cerebral ischaemic stroke:* acute focal neurological dysfunction caused by focal infarction at single or multiple sites of brain or retina, with evidence of infarction either from neuroimaging or symptom duration longer than 24 hours.
- *Intracerebral haemorrhage:* acute focal neurological disturbance caused by haemorrhage within the brain parenchyma or ventricular system.

Investigations

Investigation of suspected stroke aims to confirm the vascular nature of a lesion, distinguish infarction from haemorrhage and identify the underlying vascular disease and risk factors (Boxes 27.32 and 27.33).

Neuroimaging

Brain imaging helps to determine the cause of stroke symptoms. Non-contrast (unenhanced) computed tomography (CT) is the most widely available method of imaging the brain. Immediate brain imaging is a help and sometimes essential (Box 27.34). CT scanning is rapid, sensitive for intracranial haemorrhage (see Fig. 27.28) and can show cerebral ischaemia or other diagnoses, but does use ionising radiation. In patients with a clinical diagnosis of an acute stroke, a CT scan that shows no intracerebral haemorrhage makes an ischaemic stroke the likelier diagnosis. Soon after symptom onset, CT changes in cerebral infarction may be absent, or very subtle. Signs of infarction develop over time but small cerebral infarcts may never show up on CT imaging. CT has reasonable sensitivity for some non-stroke lesions, such as subdural haematomas, subarachnoid haemorrhage and brain tumours, but not others, such as the changes of early multiple sclerosis.

Perfusion of brain tissue can be demonstrated with CT after injection of contrast media (i.e. CT perfusion scanning). After ischaemic stroke, this technique can identify areas of brain with low perfusion that might be reversed with thrombolysis or thrombectomy.

Magnetic resonance imaging (MRI) is more sensitive than CT for changes of cerebral ischaemia and provides very detailed images of brain anatomy, although it takes longer than CT to perform (Fig. 27.30). MRI can reliably distinguish haemorrhagic from ischaemic stroke weeks after the onset. MRI uses powerful magnets that can interfere with medical devices (such as pacemakers) or metal implants, and can be claustrophobic for patients. Diffusion-weighted MRI (DWI) adds sensitivity for cerebral ischaemia compared with other MRI sequences.

CT and MRI may reveal clues as to the nature of the arterial lesion. For example, there may be a small, deep lacunar infarct indicating small-vessel disease, or a more peripheral infarct suggesting other causes (see Fig. 27.29). The location of an intracerebral haemorrhage might indicate the presence of an underlying vascular malformation, aneurysm or amyloid angiopathy.

A 'positive scan' is not needed to make a diagnosis of acute ischaemic stroke. A typical stroke syndrome with a normal CT (or a CT with no acute changes of stroke) means that an ischaemic stroke is the likeliest diagnosis. Even DWI may not show changes in up to a third of stroke patients. This means clinical skills are very important in stroke diagnosis.

Vascular imaging

Imaging of the carotid artery and of intra- and extracranial vessels can influence practice by demonstrating carotid stenosis, which guides decisions about carotid endarterectomy, and by showing major vessel occlusion in acute stroke, which guides decisions about thrombectomy. It is important to identify carotid stenosis in patients with recent ischaemic stroke or TIA because the benefit of endarterectomy is time-dependent. The presence or absence of a carotid bruit is not a reliable indicator of the degree of carotid stenosis.

The first-line imaging techniques for vessels supplying the brain can be ultrasound, CT angiography or MR angiography, depending on availability and expertise. Intra-arterial angiography is used less frequently as a primary investigation, although it is often done during neuro-interventional procedures to confirm findings from non-invasive techniques or guide treatment (Fig. 27.31). Vascular imaging can also show major

Clinical syndrome	Common symptoms	Common cause	CT scan features
Total anterior circulation syndrome (TACS)  	Combination of: Hemiparesis Higher cerebral dysfunction (e.g. aphasia) Hemisensory loss Homonymous hemianopia (damage to optic radiations)	Middle cerebral artery occlusion Embolism from heart or major vessels	Partial anterior circulation syndrome (PACS)  	Isolated motor loss (e.g. leg only, arm only, face) Isolated higher cerebral dysfunction (e.g. aphasia, neglect) Mixture of higher cerebral dysfunction and motor loss (e.g. aphasia with right hemiparesis)	Occlusion of a branch of the middle cerebral artery or anterior cerebral artery Embolism from heart or major vessels	Lacunar syndrome (LACS)  	Pure motor stroke – affects two limbs Pure sensory stroke Sensory-motor stroke No higher cerebral dysfunction or hemianopia	Thrombotic occlusion of small perforating arteries Thrombosis in situ	Posterior circulation stroke (POCS) (lateral view)  	Homonymous hemianopia (damage to visual cortex) Cerebellar syndrome Cranial nerve syndromes	Occlusion in vertebral, basilar or posterior cerebral artery territory Cardiac embolism or thrombosis in situ	
Fig. 27.29 Clinical and radiological features of the stroke syndromes. The top three diagrams show coronal sections of the brain and the bottom one shows a sagittal section. The anatomical locations of cerebral functions are shown with the nerve tracts in green. A motor (or sensory) deficit (shown by the areas shaded red) can occur with damage to the relevant cortex (PACS), nerve tracts (LACS) or both (TACS). The corresponding CT scans show horizontal slices at the level of the lesion, highlighted by the arrows.

vessel dissection, changes of cerebral vasculitis, intracranial aneurysms or arteriovenous malformations. Transcranial Doppler sonography is used in some centres to identify intracranial stenosis or occlusion.

In patients with spontaneous intracerebral haemorrhage, imaging (MRA, CTA or CT venography (CTV)) may identify an underlying macrovascular cause, e.g intracranial aneurysm, arteriovenous malformation (AVM) or venous sinus thrombosis (see Fig. 27.31).

Blood tests

The choice of blood tests should be guided by the clinical situation. A full blood count, electrolytes and renal function are usually indicated. Blood glucose (usually fasting) can diagnose unrecognised diabetes (or poor diabetes control), lipids (cholesterol fractions and triglycerides) may guide lipid-lowering therapy, and C-reactive protein or erythrocyte sedimentation rate may identify an inflammatory response (for example in giant cell arteritis or endocarditis). Clotting abnormalities are a rare cause of ischaemic or haemorrhagic stroke, and tests for thrombophilia or haemophilia without other clinical pointers rarely lead to a change in management. However, in selected patients (for example those with both venous and arterial events), tests for inherited thrombophilia or antiphospholipid antibodies may be helpful. Intracranial haemorrhage is frequently due to prescribed anticoagulants (direct oral anticoagulants or coumarins like warfarin) and monitoring may be important when reversing the effect of these agents.

Monogenic disorders are a rare cause of stroke, and genetic testing is usually guided by particular clinical or radiological syndromes (e.g. cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy, CADASIL), but needs careful discussion with patients and families so the implications of a genetic diagnosis are understood. See Box 27.33 for causes and investigations of rare causes of stroke.

27.32 Investigation of a patient with an acute stroke*

Diagnostic question	Investigation
Is it a vascular lesion?	Brain imaging
Is it ischaemic or haemorrhagic?	Brain imaging
Is it a subarachnoid haemorrhage?	CT/lumbar puncture
Is there any cardiac source of embolism?	ECG Prolonged ECG monitoring Echocardiogram
What is the underlying vascular disease, where intervention is indicated?	Ultrasound of carotids with Doppler MRA CTA Contrast angiography
What are the risk factors for stroke?	Full blood count Cholesterol Blood glucose Blood pressure
Is there an unusual cause?	ESR Serum protein electrophoresis Clotting/thrombophilia screen HIV/syphilis serology

*All of these are not necessary in all patients, and should be targeted depending on clinical syndrome and suitability for intervention.
(CT = computed tomography; CTA = computed tomographic angiography; ECG = electrocardiogram; ESR = erythrocyte sedimentation rate; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging)

Cardiac investigations

Approximately 20% of ischaemic strokes are due to embolism from the heart. The most common cause is atrial fibrillation, but prosthetic heart valves, endocarditis, other valve abnormalities and recent myocardial infarction may also lead to cardioembolism.

Atrial fibrillation can be identified on a 12-lead ECG, or more prolonged ECG recording with devices that can record between a few days and many months. A transthoracic or transoesophageal echocardiogram in selected stroke patients can identify endocarditis, atrial myxoma, intracardiac thrombus or patent foramen ovale (PFO). A PFO is a right-to-left cardiac shunt that is usually asymptomatic but can act as a conduit for thrombi from the venous system.

Management

Management (Fig. 27.32) is aimed at identifying the cause, minimising the volume of brain that is irreversibly damaged, preventing complications (Fig. 27.33), reducing the patient's disability and handicap through rehabilitation, and reducing the risk of recurrent stroke or other vascular events. With TIA there is no major persisting brain damage and disability, so the priority is to reduce the risk of stroke.

Reperfusion (thrombolysis and thrombectomy)

Rapid reperfusion in ischaemic stroke can reduce the extent of brain damage.

Intravenous thrombolysis with recombinant tissue plasminogen activator (alteplase) improves recovery if given within 4.5 hours of symptom onset to carefully selected patients. The main contraindications to thrombolysis are a high bleeding risk (recent haemorrhage, anticoagulant therapy, recent surgery or trauma at a non-compressible site) and delay to treatment: the earlier treatment is given, the greater the benefit (Fig. 27.34).

Intravenous thrombolysis fails to re-perfuse the brain in up to 30% of patients presenting with a large-vessel occlusion. Mechanical clot retrieval (thrombectomy) performed up to 6 hours after onset of symptoms can greatly improve the chances of avoiding disability in these patients (see Figs. 27.32 and 27.35). Treatment of patients presenting later, or where symptoms onset is unknown (e.g. waking from sleep), is possible if there is evidence of 'salvageable' tissue with brain imaging.

27.33 Causes and investigation of unusual causes of stroke

Cause	Investigation
Cerebral infarct	
Patent foramen ovale	Echocardiography with bubble contrast (including transoesophageal)
Premature atherosclerosis	Serum lipids
Arterial dissection	Non-invasive cervical angiography
Reversible cerebral vasoconstriction syndromes	Non-invasive cerebral angiography
Thrombophilia	Protein C, protein S Antithrombin III Factor V Leiden, prothrombin
Homocystinuria	Urinary amino acids Methionine loading test
Antiphospholipid antibody syndrome	Anticardiolipin antibodies/lupus anticoagulant
Systemic lupus erythematosus	ANA
Vasculitis	ESR CRP ANCA
CADASIL CARASIL	Genetic analysis
Mitochondrial cytopathy	Serum lactate mitochondrial genetics Muscle biopsy
Fabry disease	Alpha-galactosidase levels
Sickle-cell disorder	Sickle-cell studies
Neurovascular syphilis	Syphilis serology
HIV	HIV serology
Infective endocarditis	Blood cultures, echocardiography
Intracerebral haemorrhage	
AVM	Non-invasive cerebral angiography
Drug misuse	Drug screen (amphetamine, cocaine)
Coagulopathy	PT and APTT Platelet count
Subarachnoid haemorrhage	
Saccular ('berry') aneurysm	Non-invasive cerebral angiography
AVM	
Vertebral dissection	

(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; APTT = activated partial thromboplastin time; AVM = arteriovenous malformation; CADASIL/CARASIL = cerebral autosomal dominant/recessive arteriopathy with subcortical infarcts and leucoencephalopathy; CRP = C-reactive protein; CTA = computed tomographic angiography; ESR = erythrocyte sedimentation rate; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PT = prothrombin time).

27.34 Indications for immediate brain imaging in acute stroke

- Patient on anticoagulants or with abnormal coagulation
- Suitable for reperfusion (thrombolysis)
- Deteriorating conscious level or rapidly progressing deficits
- Suspected cerebellar haematoma, to exclude hydrocephalus

Supportive care

Rapid admission of patients to a specialised stroke unit facilitates coordinated care from a multidisciplinary team and reduces mortality and

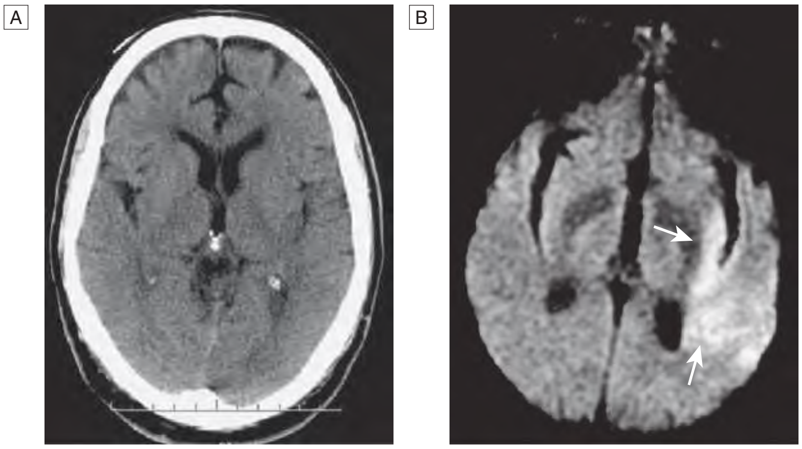

Fig. 27.30 **Computed tomography (CT) scan with corresponding magnetic resonance imaging (MRI) scan in a patient with an acute stroke.** **A** CT may show no evidence of early infarction. **B** Corresponding diffusion-weighted imaging (DWI) demonstrates changes of early infarction in the left middle cerebral artery (MCA) territory (arrows). *(A, B) Courtesy of Prof. A. Farrell and Prof. J. Wardlaw.*

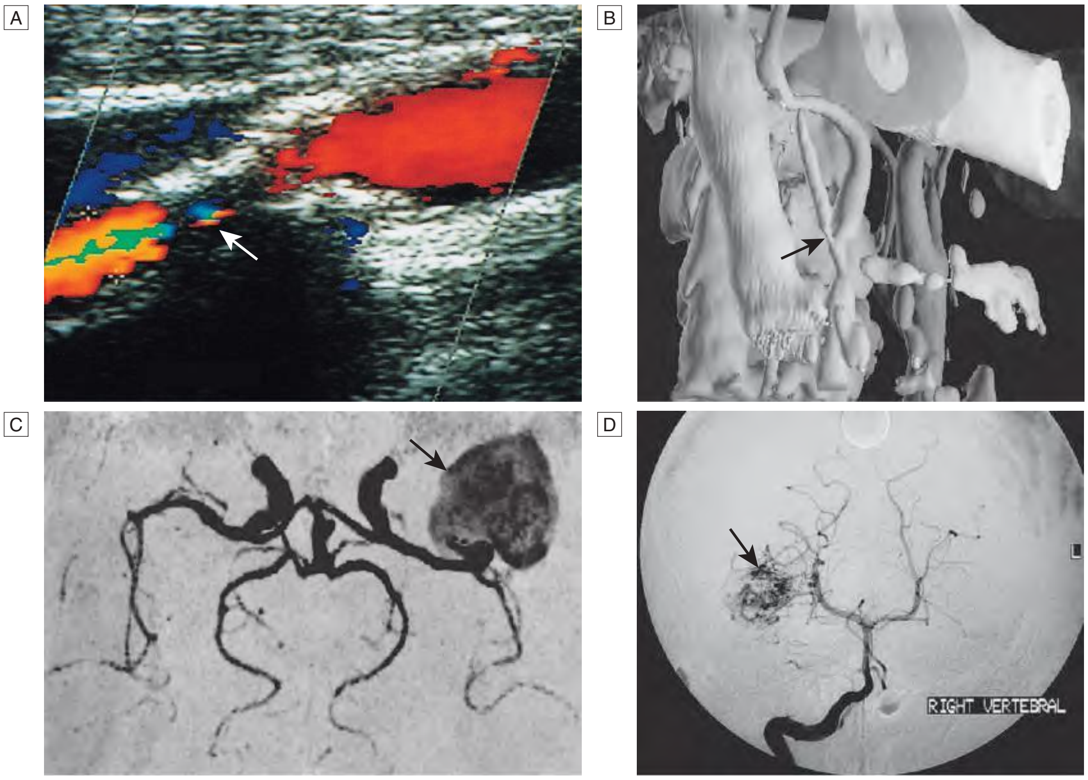

Fig. 27.31 **Different techniques for imaging blood vessels.** **A** Doppler scan showing 80% stenosis of the internal carotid artery (arrow). **B** Three-dimensional reconstruction of CT angiogram showing stenosis at the carotid bifurcation (arrow). **C** MR angiogram showing giant aneurysm at the middle cerebral artery bifurcation (arrow). **D** Intra-arterial angiography showing arteriovenous malformation (arrow). *(A–D) Courtesy of Dr D. Collie.*

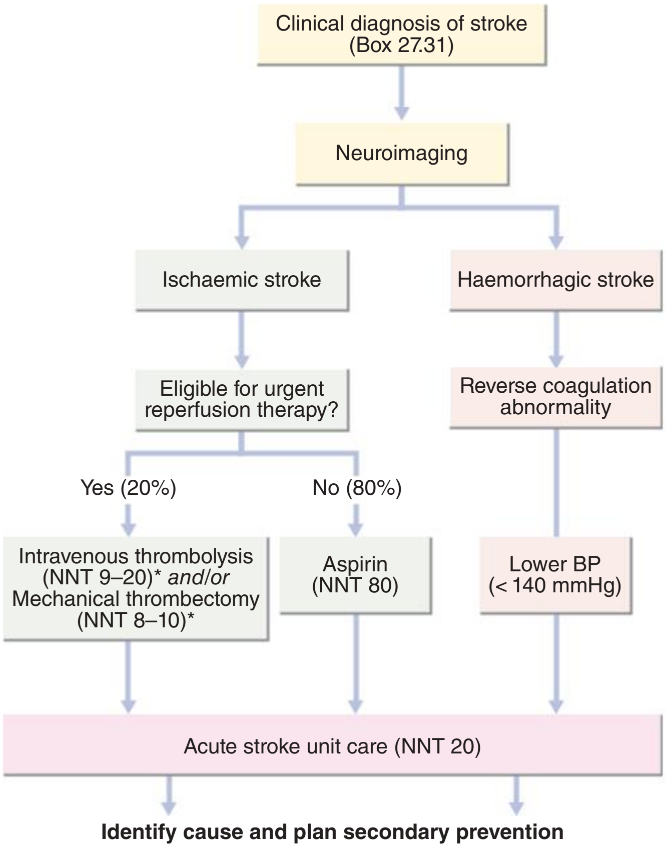
disability amongst survivors. For every 1000 patients managed in a stroke unit, an extra 50 will avoid death or long-term disability, compared to those managed in non-specialist wards. Rehabilitation should begin at the same time as acute medical management. Dysphagia is common and can be detected by an early bedside test of swallowing. This allows hydration, feeding and medication to be given safely, if necessary by nasogastric tube. In the acute phase, a checklist may be useful (Box 27.35) to ensure that all the factors that might influence outcome have been addressed.

Neurological deficits may worsen during the first few hours or days after their onset. This may be due to further infarction, haemorrhagic transformation of infarction (most commonly after thrombolysis), or the development of oedema with consequent mass effect. It is important to distinguish these patients from those who are deteriorating as a result of complications such as hypoxia, sepsis, epileptic seizures or metabolic abnormalities that may be reversed more easily. Patients with cerebellar haematomas or infarcts with mass effect may develop obstructive hydrocephalus and some will benefit from insertion of a ventricular drain or decompressive surgery. Some patients with large haematomas or infarction with massive oedema in the cerebral hemispheres may benefit from anti-oedema agents, such as mannitol, or artificial ventilation. Surgical decompression with hemicraniectomy to reduce intracranial pressure should be considered in patients where survival with severe disability is acceptable and surgery is possible within 48 hours.

Antiplatelet agents

In the absence of contraindications, aspirin (300 mg daily) should be started immediately after a major ischaemic stroke unless thrombolysis has been given, in which case it should be withheld for at least 24 hours. Aspirin reduces the risk of early ischaemic stroke recurrence and has a small but clinically worthwhile effect on disability (see Figs. 27.32 and 27.36); it may be given by rectal suppository or by nasogastric tube in dysphagic patients. In minor ischaemic stroke or TIA, two antiplatelet agents (for example clopidogrel and aspirin) for a few weeks reduce the risk of early recurrent stroke.

Considerations specific to use of anticoagulants in old age are given in Box 27.36.



Clinical diagnosis of stroke (Box 27.31)
Neuroimaging
Ischaemic stroke
Haemorrhagic stroke
Eligible for urgent reperfusion therapy?
Reverse coagulation abnormality
Yes (20%)
No (80%)
Intravenous thrombolysis (NNT 9–20)* *and/or* Mechanical thrombectomy (NNT 8–10)*
Aspirin (NNT 80)
Lower BP (< 140 mmHg)
Acute stroke unit care (NNT 20)
Identify cause and plan secondary prevention

Fig. 27.32 Emergency management of stroke. *Varies with patient selection and delay in treatment. (BP = blood pressure; NNT = number needed to treat to avoid one death or long-term disability)

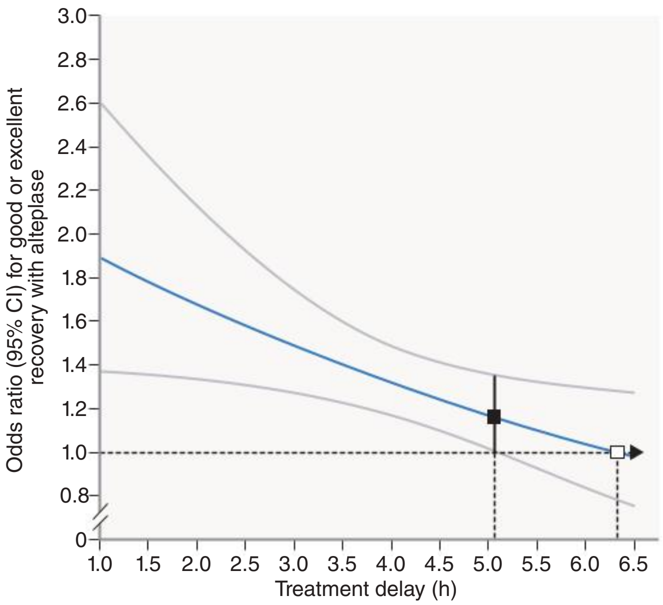


Fig. 27.34 Effect of timing of alteplase treatment on recovery from stroke. The solid blue line shows how the estimated recovery for patients given alteplase (compared with patients given control treatment) falls as the delay to treatment increases. The black box (at 5 hours) shows the point at which treatment with alteplase is no more effective than control (the lower 95% confidence interval for the estimated treatment effect first crosses 1.0 at this point). *From Emberson J, et al. Lancet 2014;384:1929–1935.*

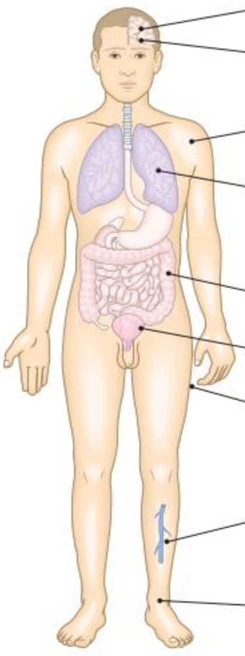

Complications	Prevention	Treatment
Epileptic seizures		Anticonvulsants
Depression and anxiety	Be alert for mood disturbance Explain the process of recovery	Antidepressants and talking therapies (e.g. cognitive behavioural therapy)
Painful shoulder	Avoid traction injury Shoulder/arm supports Physiotherapy	Physiotherapy Local glucocorticoid injections
Chest infection	Nurse semi-erect Avoid aspiration (nil by mouth, nasogastric tube, possible gastrostomy)	Antibiotics Physiotherapy
Constipation	Appropriate aperients and diet Maintain hydration	Appropriate aperients
Urinary infection	Avoid catheterisation if possible	Antibiotics
Pressure sores	Frequent turning Monitor pressure areas Avoid urine damage to skin	Nursing care Pressure-relieving mattress
Deep vein thrombosis/ pulmonary embolism	Maintain hydration Early mobilisation Pneumatic compression stockings Heparin (for high-risk patients only)	Anticoagulation
Spasticity and contractures	Maintain normal posture (support weak limbs and reposition regularly) Avoid triggers (pain, infection, bowels)	Physiotherapy Orthotics (e.g. splints) Baclofen, local Botox injections

Coagulation abnormalities

In patients with intracerebral haemorrhage, coagulation abnormalities should be reversed as quickly as possible to reduce haematoma expansion. This is a problem in patients taking anticoagulant therapy. There is no evidence that clotting factors are useful in the absence of a clotting defect.

Blood pressure

Early reduction of blood pressure (< 180 mmHg) reduces haematoma expansion and may improve the overall outcome in patients with acute intracerebral haemorrhage. Blood pressure lowering in acute ischaemic stroke does not improve later disability, but reduces intracranial haemorrhage after thrombolysis.

However, reducing blood pressure is very important in the longer term to reduce the risk of recurrent stroke.

Management of risk factors

The approaches used are summarised in Figure 27.36. The average risk of a further stroke is 5%–10% within the first week of an ischaemic stroke or TIA, 15% over the first year (including the early period) and 5% per year thereafter. Patients with ischaemic stroke or TIA should be offered long-term antiplatelet drugs and statins to lower low-density lipoprotein cholesterol (LDL-C). For patients in atrial fibrillation, the risk can be reduced substantially with oral anticoagulation with direct oral anticoagulants or warfarin (in selected patients, see Box 27.36). The risk of recurrence after both ischaemic and haemorrhagic strokes can be

27.35 How to manage a patient with acute stroke

Airway

- Perform bedside swallowing screen and consider nasogastric tube for feeding if swallowing is unsafe

Breathing

- Check respiratory rate

Circulation

- Check peripheral perfusion, pulse and blood pressure

Hydration

- If signs of dehydration, give fluids parenterally or by nasogastric tube

Nutrition

- Assess nutritional status and provide supplements if needed
- If unable to swallow, consider feeding via nasogastric tube

Medication

- If dysphagic, consider other routes for essential medications

Blood pressure

- Haemorrhagic stroke: consider lowering systolic blood pressure to 130–140 mmHg and maintain this blood pressure for at least 7 days
- Ischaemic stroke: unless there is heart or renal failure, evidence of hypertensive encephalopathy or aortic dissection, do not lower blood pressure abruptly
- Check blood glucose and treat if diabetes is diagnosed
- Avoid hypoglycaemia

Temperature

- If pyrexial, investigate and treat underlying cause
- Control temperature with antipyretics

Pressure areas

- Reduce risk of skin breakdown:
  Treat infection
  Maintain nutrition
  Provide pressure-relieving mattress
  Turn immobile patients regularly

Incontinence

- Check for constipation and urinary retention; treat these appropriately
- Avoid urinary catheterisation unless patient is in acute urinary retention or incontinence is threatening pressure areas

Prevention of deep vein thrombosis

- Consider intermittent pneumatic compression stockings in immobile patients

Mobilisation

- Avoid bed rest after the first 24 hours

reduced by blood pressure reduction, even for those with relatively ‘normal’ blood pressures. Patients should stop smoking. The evidence for change in diet or increasing exercise is weaker, but it is probable these interventions reduce recurrent stroke.

Carotid endarterectomy and arterial angioplasty

Some patients with a carotid territory ischaemic stroke or TIA have >50% stenosis of the carotid artery on the side of the brain lesion. These patients have a greater than average risk of stroke recurrence. For those without major residual disability, removal of the stenosis by carotid endarterectomy reduces the risk of recurrent stroke although the operation itself carries about a 3%–4% stroke risk, depending on the surgical centre. Surgery is most effective in patients with more severe stenoses (70%–99%) and when it is performed within the first couple of weeks after the TIA or ischaemic stroke. Carotid angioplasty and stenting are technically feasible but have not been shown to be as effective as endarterectomy for the majority of eligible patients. Endarterectomy of asymptomatic carotid stenosis reduces stroke risk, but it has a smaller absolute benefit. Whilst stenting of other arteries (vertebral or intracranial) could reduce stroke incidence, at present there is no evidence to support their use in clinical practice.

Rehabilitation

Stroke survivors are often disabled by reduced mobility or upper limb weakness, impaired communication, cognitive impairment, dyspraxia, poor coordination or visual impairment. Around a third of patients develop dementia after stroke. A minority have persistent dysphagia and some need long-term enteral feeding with a gastrostomy tube. Other long-term stroke complications include neuropathic pain (particularly common after thalamic stroke), limb spasticity, shoulder pain, epilepsy, incontinence, fatigue and anxiety or depression.

The purpose of rehabilitation is to maximise functional recovery and prevent complications. The speed and degree of recovery varies between individuals. Severe strokes (total anterior circulation syndrome or NIHSS score >15) are more likely to cause severe disability and loss of independent living. Other predictors of poor recovery are older age, pre-existing disability, multi-morbidity and pre-existing cognitive impairment.

The goals set during rehabilitation should be achievable, and reached by discussion between the patient and a multidisciplinary team on a dedicated stroke unit, including doctors, nurses, physiotherapists, speech and language therapists, occupational therapists, psychologists and dieticians. Supportive family and social networks are important.

There are three main phases of recovery. Early recovery (first few days) is due to resolution of cerebral oedema and cerebral reperfusion. The second phase – ‘neuroplasticity’ – is when new areas of brain take over from damaged areas of brain. This ‘rewiring’ can occur for a year or even later after stroke, but most happens within the first few months. Intensive rehabilitation should begin as early as possible after the first 24 hours, because very early mobilisation (<24 hrs) may be harmful. Repetitive practice of lost skills has been shown to increase neuroplasticity. The third phase is adaptive recovery. In this period the patient may learn new strategies to live with their disability, and provision can be made for mobility aids, communication aids, or adaptations to the home. Intense therapy in the longer term may be beneficial to some patients and is an area of active research.

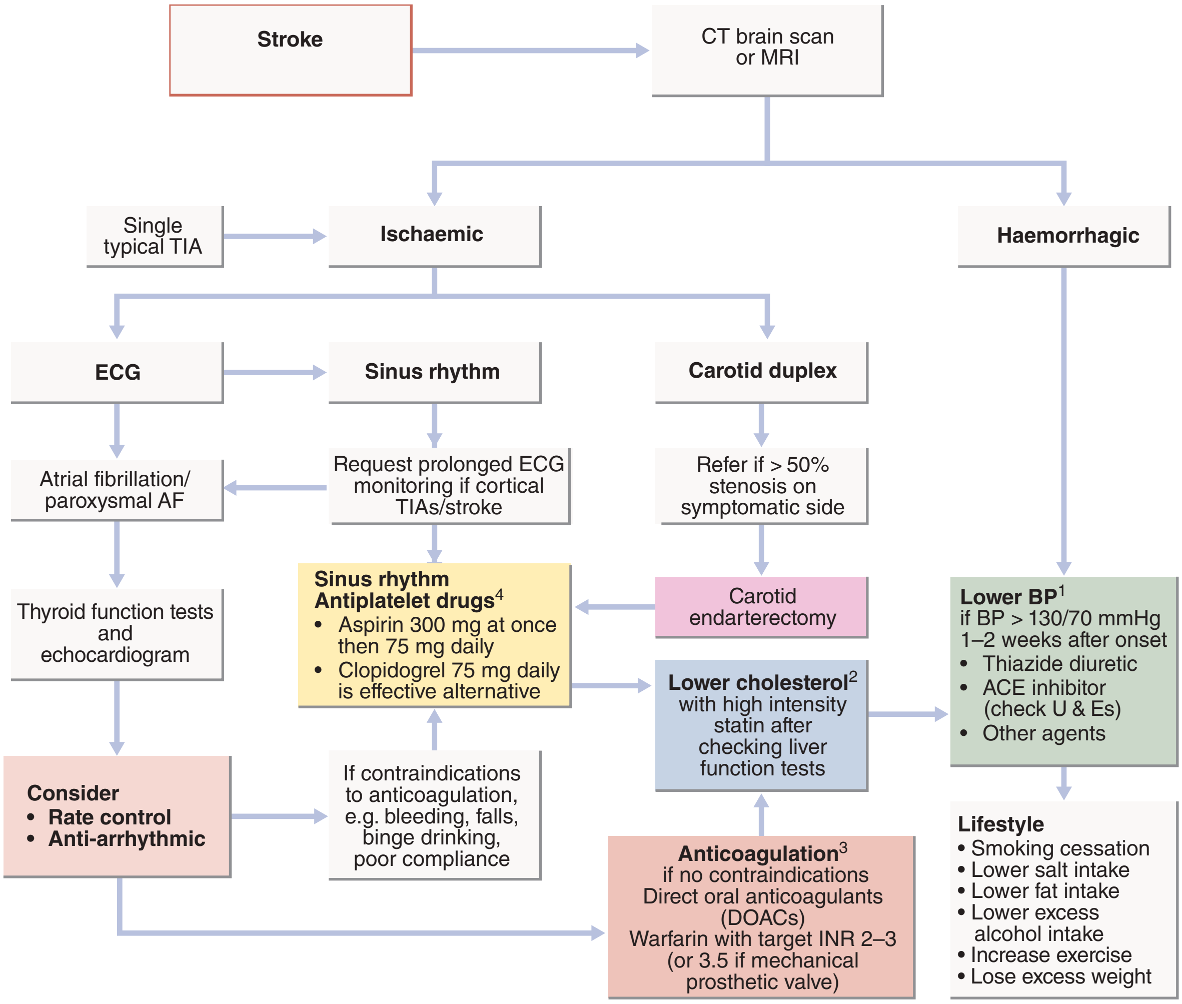
It is important not to underestimate the long-term emotional and financial impacts of stroke. Many stroke survivors face an initial loss of identity, loss of income and relationship strain. It is common for stroke survivors to feel fear, anxiety, frustration, anger, sadness and a sense of grief over physical and mental losses. Stroke survivors hoping to return to education or work need specialist vocational support.

Barriers to effective rehabilitation include physical illness: post-stroke pneumonia or delirium, which can delay rehabilitation sessions; pre-existing cognitive impairment or physical frailty; poor motivation and apathy (common in non-dominant hemisphere strokes); fatigue; depression; or pain. When improvements in lost function slow down, the focus of therapy shifts to adaptive recovery. Milestones can be used to discuss rehabilitation goals with patients and their carers and to set out realistic expectations for recovery. Physical milestones include sitting balance (e.g. 1 minute unsupported sit), followed by standing balance (e.g. 1 minute), followed by stepping (e.g. 10 steps on the spot) and then walking (e.g. 10 metres).

Research in technologies to assist stroke rehabilitation is ongoing, including transcranial direct current stimulation and vagal stimulators for motor recovery and mirror therapy for limb pain and visuo-spatial neglect.

Causes of ischaemic stroke

Large artery atherosclerosis, small vessel disease and cardioembolism from AF are the commonest causes of ischaemic stroke. Carotid or vertebral artery dissection occasionally leads to stroke. The presenting history often includes minor injury and face or neck pain. After confirmation on angiography (MRA or CTA), treatment is with either antiplatelet drugs or anticoagulation (the latter are more effective). The cause of dissection



Stroke
CT brain scan or MRI
Single typical TIA
Ischaemic
Haemorrhagic
ECG
Sinus rhythm
Carotid duplex
Atrial fibrillation/ paroxysmal AF
Request prolonged ECG monitoring if cortical TIAs/stroke
Refer if > 50% stenosis on symptomatic side
Thyroid function tests and echocardiogram
Sinus rhythm Antiplatelet drugs4
• Aspirin 300 mg at once then 75 mg daily
• Clopidogrel 75 mg daily is effective alternative
Carotid endarterectomy
Lower BP1 if BP > 130/70 mmHg 1–2 weeks after onset
• Thiazide diuretic
• ACE inhibitor (check U & Es)
• Other agents
Lower cholesterol2 with high intensity statin after checking liver function tests
Consider
• Rate control
• Anti-arrhythmic
If contraindications to anticoagulation, e.g. bleeding, falls, binge drinking, poor compliance
Anticoagulation3 if no contraindications Direct oral anticoagulants (DOACs) Warfarin with target INR 2–3 (or 3.5 if mechanical prosthetic valve)
Lifestyle
• Smoking cessation
• Lower salt intake
• Lower fat intake
• Lower excess alcohol intake
• Increase exercise
• Lose excess weight

Fig. 27.36 **Strategies for secondary prevention of stroke.** [1]Lower blood pressure with caution in patients with postural hypotension, renal impairment or severe bilateral carotid stenosis. [2]Other statins can be used as an alternative to simvastatin in patients on warfarin or digoxin. [3]Warfarin and aspirin have been used in combination in patients with prosthetic heart valves. [4]The combination of aspirin and clopidogrel is indicated short term (≤ 21 days) in patients with high-risk TIA (ABCD2 score > 4) or mild stroke (NIHSS < 3) and low bleeding risk. Afterwards these patients should continue either aspirin or clopidogrel long term. (ACE = angiotensin-converting enzyme; AF = atrial fibrillation; BP = blood pressure; CT = computed tomography; ECG = electrocardiogram; INR = international normalised ratio; MRI = magnetic resonance imaging; TIA = transient ischaemic attack; U & Es = urea and electrolytes)

27.36 Anticoagulation in old age

- Randomised trials of anticoagulation versus aspirin in older people with atrial fibrillation demonstrate a halving of the risk of stroke from about 4% to about 2% per year. Any increased risk of bleeding is much smaller.
- **AF and increased risk of stroke**: older age and previous stroke increase the risk of stroke in the presence of atrial fibrillation, and bleeding risk with anticoagulation.
- **Falls risk**: older patients are more prone to falls, including head injuries, which may increase bleeding risk.

is unknown in most cases, but collagen disorders, e.g. Ehlers–Danlos syndrome (type 4), are occasionally responsible.

Giant cell arteritis, a vasculitis of large and medium-sized blood vessels, may present with transient monocular blindness, usually with head tenderness, shoulder pain or jaw claudication on chewing. It is important to identify because blindness can be prevented with steroids. Other large artery vasculitis can very rarely present with stroke.

Causes of intracerebral haemorrhage

Most intracerebral haemorrhages result from disease of the small cerebral blood vessels, either due to sporadic small vessel disease or amyloid angiopathy. Anticoagulants, given for AF or metal prosthetic heart valves, increase the risk of intracerebral haemorrhage but almost always to a smaller degree than their reduction in the risk of ischaemic stroke.

Arteriovenous or cavernous malformations (‘cavernomas’) are more commonly discovered after intracerebral haemorrhage in younger people. To reduce the risk of further haemorrhage, it is possible to treat some of these malformations with surgery or radio-surgery. Arteriovenous malformation can be treated by surgical removal, by ligation of the blood vessels that feed or drain the lesion, or most often by radiological injection of material to occlude the fistula or draining veins. However, treatment of these malformations when they are asymptomatic probably leads to more harm than benefit.

Subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH) (see Fig. 27.27) affects about 6 per 100 000 of the population per year. SAH is more common in women, in older people and in those with a family history, or vascular risk factors (particularly smoking and hypertension). About 30% of patients with an aneurysmal SAH die within a month of their bleed; untreated survivors have a recurrence (or rebleed) rate of about 40% in the first 4 weeks.

Most SAHs (85%) are due to saccular or 'berry' aneurysms at bifurcations of cerebral arteries (see Fig. 27.13), particularly in the circle of Willis. The most common sites are in the anterior communicating artery (30%), posterior communicating artery (25%) and middle cerebral artery (20%). There is an increased risk in first-degree relatives of those with saccular aneurysms, in patients with polycystic kidney disease and congenital connective tissue disorders such as Ehlers–Danlos syndrome. A minority of SAHs are not associated with aneurysms – the clinical syndrome of 'peri-mesencephalic haemorrhage', which have a characteristic appearance on CT and a benign prognosis. Small cortical surface SAH is thought to be due to amyloid angiopathy. Around 5% of SAHs are due to arteriovenous malformations or vertebral artery dissection.

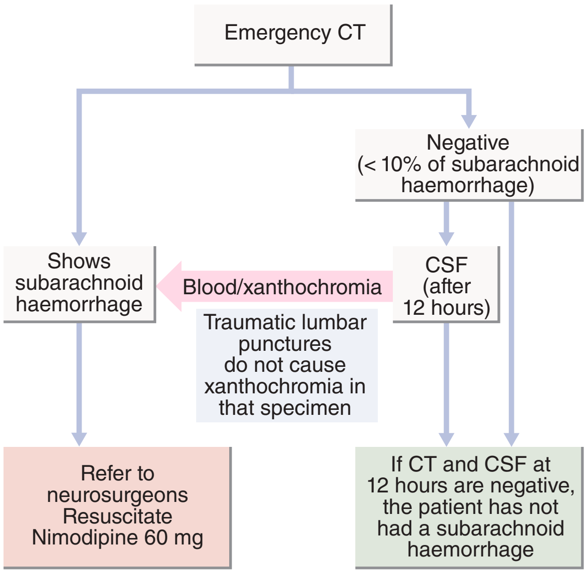
Clinical features

SAH usually presents with a sudden, severe, 'thunderclap' headache, which is usually persistent, often accompanied by vomiting, raised blood pressure and neck stiffness or pain. It can occur spontaneously, on physical exertion, straining or during sex. There may be loss of consciousness, so SAH should be considered if a patient is found comatose. About 1 patient in 8 with a sudden severe headache has SAH and, in view of this, all who present in this way require investigation to exclude it (Fig. 27.37).

On examination, the patient may be distressed, in pain, with photophobia. There may be neck stiffness due to subarachnoid blood, but this may take some hours to develop. Focal hemisphere signs, such as hemiparesis or aphasia, may be present at onset if there is an associated intracerebral haematoma. A third nerve palsy may be present due to local pressure from an aneurysm of the posterior communicating artery, and patients presenting with a painful third nerve palsy should be investigated urgently for the presence of an expanding aneurysm. Fundoscopy may reveal a subhyaloid haemorrhage, which represents blood tracking along the subarachnoid space around the optic nerve.

Investigations

The diagnosis of SAH can usually be made by a timely CT read by an expert radiologist, but a negative result does not completely exclude it, since small amounts of blood in the subarachnoid space may not be detected by CT, especially if the presentation is delayed by more than a day (see Fig. 27.37). Lumbar puncture should be performed 12 hours after symptom onset if possible, to allow detection of xanthochromia. If either of these tests is positive, CT or digital subtraction cerebral angiography (see Fig. 27.31) is needed to identify an aneurysm.



Emergency CT
Negative
(< 10% of subarachnoid haemorrhage)
Shows subarachnoid haemorrhage
Blood/xanthochromia
CSF (after 12 hours)
Traumatic lumbar punctures do not cause xanthochromia in that specimen
Refer to neurosurgeons
Resuscitate
Nimodipine 60 mg
If CT and CSF at 12 hours are negative, the patient has not had a subarachnoid haemorrhage

Fig. 27.37 Investigation of subarachnoid haemorrhage. (CSF = cerebrospinal fluid; CT = computed tomography)

Management

Nimodipine is given to prevent delayed cerebral ischaemia in the acute phase. Insertion of platinum coils into an aneurysm (via an endovascular procedure) or surgical clipping of the aneurysm neck reduces the risk of both early and late recurrent SAH. Coiling is associated with fewer perioperative complications and better outcomes than surgical clipping: where feasible, it is now the procedure of first choice. Treatment may also be needed for complications of SAH, which include obstructive hydrocephalus (that may require drainage via a shunt), delayed cerebral ischaemia due to vasospasm (which may be treated with vasodilators), hyponatraemia (best managed by fluid restriction) and systemic complications associated with immobility, such as chest infection and venous thrombosis.

Rehabilitation

The pattern of recovery after subarachnoid haemorrhage is different to ischaemic or haemorrhagic stroke, perhaps due to a more widespread brain injury. Even those who make a good physical recovery from a mild SAH often have problems with headache, thinking, fatigue and change in personality. Physical disabilities due to hemiparesis, arm or leg weakness or incoordination may relate to ischaemic or haemorrhagic lesions following aneurysm rupture.

Cerebral venous disease

Thrombosis of the cerebral veins and venous sinuses (cerebral venous thrombosis) is much less common than arterial thrombosis. The main causes are listed in Box 27.37. It may be idiopathic, associated with pregnancy, infection of the cranial sinuses, severe dehydration, or due to other acquired or inherited thrombophilias.

Clinical features

Cerebral venous sinus thrombosis usually presents with symptoms of raised intracranial pressure, seizures and focal neurological symptoms. The clinical features vary according to the sinus involved (Box 27.38 and see Fig. 27.14). Cortical vein thrombosis presents with focal cortical deficits such as aphasia and hemiparesis (depending on the area affected), and epilepsy (focal or generalised). Occlusion of the larger veins may present with severe illness, but also with a milder illness of headache and papilloedema.

Investigations and management

MR venography demonstrates a filling defect in the affected vessel. Anticoagulation, initially with heparin followed by warfarin, is beneficial, even in the presence of venous haemorrhage. In selected patients, endovascular thrombolysis has been advocated. Management of underlying

i 27.37 Causes of cerebral venous thrombosis

Predisposing systemic causes

- Dehydration
- Pregnancy
- Behçet disease
- Thrombophilia
- Hypotension
- Oral contraceptive use

Local causes

- Paranasal sinusitis
- Meningitis, subdural empyema
- Penetrating head and eye wounds
- Facial skin infection
- Otitis media, mastoiditis
- Skull fracture

27.38 Clinical features of cerebral venous thrombosis

Cavernous sinus thrombosis

- Proptosis, ptosis, headache, external and internal ophthalmoplegia, papilloedema, reduced sensation in trigeminal first division
- Often bilateral, patient ill and febrile

Superior sagittal sinus thrombosis

- Headache, papilloedema, seizures
- Clinical features may resemble idiopathic intracranial hypertension (p. 1231)
- May involve veins of both hemispheres, causing motor and sensory focal deficits

Transverse sinus thrombosis

- Hemiparesis, seizures, papilloedema
- May spread to jugular foramen and involve cranial nerves 9, 10 and 11

causes and complications, such as persistently raised intracranial pressure, is important.

Epilepsy

A seizure can be defined as the occurrence of signs and/or symptoms due to abnormal, excessive or synchronous neuronal activity in the brain. The lifetime risk of an isolated seizure is about 5%, although incidence is highest at the extremes of age. Epilepsy is the tendency to have unprovoked seizures. While the prevalence of active epilepsy in European countries is about 0.5%, this figure varies globally and can be influenced by the prevalence of parasitic illnesses such as cysticercosis. A recent change in definition allows the diagnosis of epilepsy to be made after a single seizure with a high risk of recurrence (e.g. a single seizure in the presence of a cortical lesion). Such changes may lead to an observed increase in epilepsy incidence.

Historical terms such as 'grand mal' (implying tonic–clonic seizures) and 'petit mal' (intended originally to mean 'absence seizures' but commonly misused to describe 'anything other than grand mal') have been superseded. Subsequent revisions, including terms such as 'complex partial' and 'simple partial', have been imprecise and carry little information about underlying pathology, treatment or prognosis. The modern equivalents for these terms will be given below, but it is preferable to adhere to the 2017 iteration of the International League Against Epilepsy's classification (Box 27.39).

27.39 Classification of seizures (2025 International League Against Epilepsy classification)

Generalised onset

Motor

- Tonic–clonic (in any combination)

- Emotional
- Sensory

Focal to bilateral tonic–clonic

Unknown onset

Motor

- Tonic–clonic
- Epileptic spasms

Non-motor

- Behavioural arrest

Pathophysiology

To function normally, the brain must maintain a continual balance between excitation and inhibition, remaining responsive to the environment while avoiding continued unrestrained spontaneous activity. The inhibitory transmitter gamma-aminobutyric acid (GABA) is particularly important, acting on ion channels to enhance chloride inflow and reducing the chances of action potential formation. Excitatory amino acids (glutamate and aspartate) allow influx of sodium and calcium, producing the opposite effect. It is likely that many seizures result from an imbalance between this excitation and inhibition. Intracellular recordings during seizures demonstrate a paroxysmal depolarisation shift in neuronal membrane potential, an upshift in internal potential predisposing to recurrent action potentials. In vivo, epileptic cortex shows repetitive discharges involving large groups of neurons.

Focal epilepsy

Seizures may be related to a localised disturbance in the cortex, becoming manifest in the first instance as focal seizures. Any disturbance of cortical architecture and function can precipitate this, whether focal infection, tumour, hamartoma or trauma-related scarring. If focal seizures remain localised, the symptoms experienced depend on which cortical area is affected. If areas in the temporal lobes become involved, then awareness of the environment becomes impaired but without associated tonic–clonic movements. When both hemispheres become involved, the seizure becomes generalised (Fig. 27.38).

Generalised epilepsies

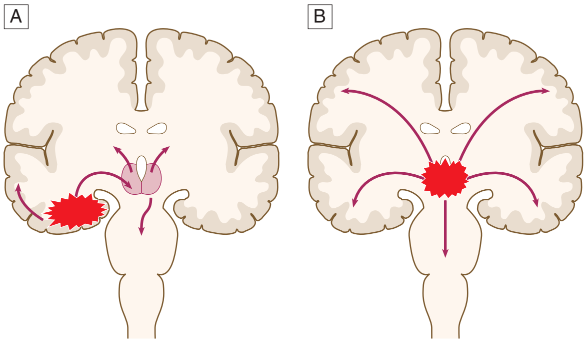
The new terminology is genetic generalised epilepsies (GGEs) (previously idiopathic generalised epilepsies, and many prefer to still use this term) to reflect their likely cause. These seizures are generalised at onset, abnormal activity probably originating in the central mechanisms controlling cortical activation (see Fig. 27.38) and spreading rapidly. This group constitutes around 30% of all epilepsy and is likely to reflect widespread disturbance of structure or function. GGEs almost always become apparent before the age of 35.

Seizure activity is usually apparent on EEG as spike and wave discharges (see Fig. 27.17). Other generalised seizures may involve merely brief loss of awareness (absence seizures), single jerks (myoclonus) or loss of tone (atonic seizures), as detailed in Box 27.39.

Clinical features

Seizure type and epilepsy type

Patients can experience more than one type of seizure attack, and it is important to document each attack type and the patient's age at its



Focal seizure
± secondary generalisation

Primary generalised seizure

Fig. 27.38 The pathophysiological classification of seizures. **A** A focal seizure originates from a paroxysmal discharge in a focal area of the cerebral cortex (often the temporal lobe); the seizure may subsequently spread to the rest of the brain (secondary generalisation) via diencephalic activating pathways. **B** In genetic generalised epilepsies (GGEs) the abnormal electrical discharges originate from the diencephalic activating system and spread simultaneously to all areas of the cortex.

i 27.40 Trigger factors for seizures

- Sleep deprivation
- Missed doses of antiseizure medications in treated patients
- Alcohol (particularly withdrawal)
- Recreational drug misuse
- Physical and mental exhaustion
- Flickering lights, including TV and computer screens (generalised epilepsy syndromes only)
- Intercurrent infections and metabolic disturbances
- Uncommon: loud noises, music, reading, hot baths

onset, along with its frequency, duration and typical features. Any triggers should be identified (Box 27.40). The type of seizure, other clinical features and investigations can then be used to determine the epilepsy syndrome, as discussed below. Where there is doubt about the type, this is best stated and a full classification should be deferred until the evolution of the clinical features clarifies the picture.

To classify seizure type, the clinician should ask firstly whether there is a focal onset, and secondly whether the seizures conform to one of the recognised patterns (see Box 27.39). Epilepsy that starts in patients beyond their mid-thirties will almost invariably reflect a focal cerebral event. Where activity remains focal, the classification will be obvious. With generalised tonic–clonic seizures, a focal onset will be heralded by positive neurological symptoms and signs corresponding to the normal function of that area. Occipital onset causes visual changes (lights and blobs of colour), temporal lobe onset causes false recognition (déjà vu), sensory strip involvement causes sensory alteration (burning, tingling) and motor strip involvement causes jerking.

Alternatively, patients report a previous local cortical insult, and it may be reasonably (but not invariably) inferred that this is the seat of epileptogenesis.

Focal seizures

The classification of focal seizures is shown in Box 27.39. They are caused by localised cortical activity. The localisation of such symptoms is described above. A spreading pattern of seizure may occur, the abnormal sensation spreading much faster (in seconds) than a migrainous focal sensory attack.

Awareness may become impaired if spread occurs to the temporal lobes (previously 'complex partial seizure'). Patients stop and stare blankly, often blinking repetitively, making smacking movements of their lips or displaying other automatisms, such as picking at their clothes. After a few minutes consciousness returns but the patient may be muddled and feel drowsy for a period of up to an hour. The age of onset,

- Human immunodeficiency virus (HIV)

Inflammatory

- Autoimmune encephalopathies (e.g. anti-voltage-gated potassium channel antibodies, anti-NMDA receptor antibodies)
- Sarcoidosis
- Vasculitis

(NMDA = N-methyl-D-aspartate).

preceding aura, longer duration and post-ictal symptoms usually make these easy to differentiate from childhood absence seizures (see below).

Seizures arising from the anterior parts of the frontal lobe may produce bizarre behaviour patterns, including limb posturing, sleep walking or even frenetic, ill-directed motor activity with incoherent screaming. Video EEG may be necessary to differentiate these from psychogenic attacks (which are more common), but abruptness of onset, stereotyped nature, relative brevity and nocturnal preponderance may indicate a frontal origin. Causes of focal seizures are given in Box 27.41.

Generalised seizures

Tonic–clonic seizures An initial 'aura' may be experienced by the patient, depending on the cortical area from which the seizure originates (as above). The patient then becomes rigid (tonic) and unconscious, falling heavily if standing ('like a log') and risking facial injury. During this phase, breathing stops and central cyanosis may occur. As cortical discharges reduce in frequency, jerking (clonic) movements emerge for 2 minutes at most. Afterwards, there is a flaccid state of deep coma, which can persist for some minutes, and on regaining awareness the patient may be confused, disorientated and/or amnesic. During the attack, urinary incontinence and tongue-biting may occur. A severely bitten, bleeding tongue after an attack of loss of consciousness is pathognomonic of a generalised seizure, but less marked lingual injury can occur in syncope. Subsequently, the patient usually feels unwell and sleepy, with headache and myalgia. Witnesses are usually frightened by the event, often believe the person to be dying, and may struggle to give a clear account of the episode. Some may not describe the tonic or clonic phase and may not mention cyanosis or tongue-biting. In less typical episodes, post-ictal delirium, or sequelae such as headache or myalgia, may be the main

- Creutzfeldt–Jakob disease (rarely)

pointers to the diagnosis. Causes of generalised tonic–clonic seizures are listed in Box 27.42.

Absence seizures Absence seizures (previously ‘petit mal’) always start in childhood. The attacks are rarely mistaken for focal seizures because of their brevity. They can occur so frequently (20–30 times a day) that they are mistaken for daydreaming or poor concentration in school.

Myoclonic seizures These are typically brief, jerking movements, predominating in the arms. In epilepsy, they are more marked in the morning or on awakening from sleep, and tend to be provoked by fatigue, alcohol or sleep deprivation.

Atonic seizures These are seizures involving brief loss of muscle tone, usually resulting in heavy falls with or without loss of consciousness. They occur only in the context of epilepsy syndromes that involve other forms of seizure.

Tonic seizures These are associated with a generalised increase in tone and an associated loss of awareness. They are usually seen as part of an epilepsy syndrome and are unlikely to be isolated.

Clonic seizures Clonic seizures are similar to tonic–clonic seizures. The clinical manifestations are similar but there is no preceding tonic phase.

Seizures of uncertain generalised or focal nature

Epileptic spasms While these are highlighted in the classification system, they are unusual in adult practice and occur mainly in infancy. They signify widespread cortical disturbance and take the form of marked contractions of the axial musculature, lasting a fraction of a second but recurring in clusters of 5–50, often on awakening.

i 27.43 Electroclinical epilepsy syndromes

Adolescence to adulthood

- Juvenile absence epilepsy (JAE)
- Juvenile myoclonic epilepsy (JME)
- Epilepsy with generalised tonic–clonic seizures alone
- Progressive myoclonus epilepsies (PMEs)
- Autosomal dominant epilepsy with auditory features (ADEAF)
- Other familial temporal lobe epilepsies

Less specific age relationship

- Familial focal epilepsy with variable foci (childhood to adult)
- Reflex epilepsies

Distinctive constellations

- Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS)
- Rasmussen syndrome
- Gelastic (from the Greek word for laughter) seizures with hypothalamic hamartoma
- Hemiconvulsion–hemiplegia–epilepsy

Epilepsies with structural–metabolic causes

- Malformations of cortical development (hemimegalencephaly, heterotopias etc.)
- Neurocutaneous syndromes (tuberous sclerosis complex, Sturge–Weber etc.)
- Tumour
- Infection
- Trauma
- Angioma
- Perinatal insults
- Stroke

Epilepsies of unknown cause

Conditions with epileptic seizures not needing long-term treatment

- Benign neonatal seizures (BNS)
- Febrile seizures (FS)

Epilepsy syndromes

Many patients with epilepsy fall into specific patterns, depending on seizure type(s), age of onset and treatment responsiveness: the so-called electroclinical syndromes (Box 27.43). It is anticipated that genetic testing will ultimately demonstrate similarities in molecular pathophysiology.

Box 27.44 highlights the more common epilepsy syndromes, which are largely of early onset and are sensitive to sleep deprivation, hyperventilation, alcohol and photic stimulation. Epilepsies that do not fit into any of these diagnostic categories can be delineated firstly on the basis of the presence or absence of a known structural or metabolic condition (presumed cause), and then on the basis of the primary mode of seizure onset (generalised versus focal).

Investigations

Single seizure

All patients with transient loss of consciousness should have a 12-lead ECG. Where seizure is suspected or definite, patients should have cranial imaging with either MRI or CT, although the yield is low unless focal signs are present. EEG may help to assess prognosis once a firm diagnosis has been made. The recurrence rate after a first seizure is approximately 40% and most recurrent attacks occur within a month or two of the first. Further seizures are less likely if an identified trigger can be avoided (see Box 27.40).

Other investigations for infective, toxic and metabolic causes (Box 27.45) may be appropriate. An EEG performed immediately after a seizure may be more helpful in showing focal features than if performed after a delay.

Epilepsy

The same investigations are required in a patient with epilepsy (see Box 27.45). The EEG may help to establish the type of epilepsy and guide therapy. Investigations should be revisited if the epilepsy is intractable to treatment.

27.44 Common generalised epilepsy syndromes

Syndrome	Age of onset	Type of seizure	EEG features	Treatment	Prognosis
Childhood absence epilepsy	4–8 years	Frequent brief absences	3/sec spike and wave	Ethosuximide Sodium valproate Levetiracetam	40% develop GTCS, 80% remit in adulthood
Juvenile absence epilepsy	10–15 years	Less frequent absences than childhood absence	Poly-spike and wave	Sodium valproate* Levetiracetam	80% develop GTCS, 80% seizure-free in adulthood
Juvenile myoclonic epilepsy	15–20 years	GTCS, absences, morning myoclonus	Poly-spike and wave, photosensitivity	Sodium valproate* Levetiracetam	90% remit with ASMs but relapse if ASM withdrawn
GTCS on awakening	10–25 years	GTCS, sometimes myoclonus	Spike and wave on waking and sleep onset	Sodium valproate Levetiracetam	65% controlled with ASMs but relapse off treatment

*Consider alongside other ASMs in light of reproductive risks, consulting national regulatory advice and clinical guidelines.
(ASM = antiseizure medication; GTCS = generalised tonic–clonic seizure)

27.45 Investigation of epilepsy

From where is the epilepsy arising?

- Standard EEG
- Sleep EEG
- EEG with special electrodes (foramen ovale, subdural)

What is the cause of the epilepsy?

Structural lesion?

- CT
- MRI

Metabolic disorder?

- Urea and electrolytes
- Liver function tests
- Blood glucose
- Serum calcium, magnesium

Inflammatory or infective disorder?

- Full blood count, erythrocyte sedimentation rate, C-reactive protein
- Chest X-ray
- Serology for syphilis, HIV, collagen disease
- CSF examination

Are the attacks truly epileptic?

- Ambulatory EEG
- Videotelemetry

(CSF = cerebrospinal fluid; CT = computed tomography; EEG = electroencephalography; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging)

27.46 Indications for brain imaging in epilepsy

- Epilepsy starting after the age of 16 years
- Seizures having focal features clinically
- Electroencephalogram showing a focal seizure source
- Control of seizures difficult or deteriorating

Inter-ictal EEG is abnormal in only about 50% of patients with recurrent seizures, so it cannot be used to exclude epilepsy. The sensitivity can be increased to about 85% by prolonging recording time and including a period of natural or drug-induced sleep, but this does not replace a well-taken history. Ambulatory EEG recording or video EEG monitoring may help with differentiation of epilepsy from other disorders if attacks are sufficiently frequent.

Indications for imaging are summarised in Box 27.46. Imaging cannot establish a diagnosis of epilepsy but identifies any structural cause. It is not required if a confident diagnosis of a recognised GGE syndrome (e.g. juvenile myoclonic epilepsy) is made. While CT excludes a major structural cause of epilepsy, MRI is required to demonstrate subtle changes such as hippocampal sclerosis, which may direct or inform surgical intervention.

Management

It is important to explain the nature and cause of seizures to patients and their relatives, and to instruct relatives in the first aid management of seizures (Box 27.47). Many people with epilepsy feel stigmatised and may become unnecessarily isolated from work and social life. It is important to emphasise that epilepsy is a common disorder that affects 0.5%–1% of the population, and that full control of seizures can be expected in approximately 70% of patients (Box 27.48).

27.47 How to administer first aid for seizures

- Move the person away from danger (fire, water, machinery, furniture)
- After convulsions cease, turn the person into the 'recovery' position (semi-prone)
- Ensure the airway is clear but do **NOT** insert anything in the mouth (tongue-biting occurs at seizure onset and cannot be prevented by observers)
- If convulsions continue for more than 5 mins or recur without the person regaining consciousness, summon urgent medical attention
- Do not leave the person alone until fully recovered (drowsiness and delirium can persist for up to 1 hr)

27.48 Epilepsy: outcome after 20 years

- 50% are seizure-free, without drugs, for the previous 5 years
- 20% are seizure-free for the previous 5 years but continue to take medication
- 30% continue to have seizures in spite of antiepileptic therapy

Immediate care

Little can or needs to be done for a person during a convulsive seizure except for first aid and common-sense manoeuvres to limit damage or secondary complications (see Box 27.47). Advice should be given that on no account should anything be inserted into the patient's mouth. The management of status epilepticus is described on page 1168.

Lifestyle advice

Patients should be advised to avoid activities where they might place themselves or others at risk if they have a seizure. This applies at work, at home and at leisure. At home, only shallow baths (or showers) should be taken. Prolonged cycle journeys should be discouraged until reasonable freedom from seizures has been achieved. Activities involving prolonged proximity to water (swimming, fishing or boating) should always be carried out in the company of someone who is aware of the risks and the potential need for rescue measures. Driving regulations vary between countries and the patient should be made aware of these (Box 27.49). Certain occupations, such as firefighter or airline pilot, are not open to those with a previous or active diagnosis of epilepsy; further information is available from epilepsy support organisations.

The risk of harm from epilepsy should be discussed around the time of diagnosis. In particular epilepsy is associated with a very small, but potentially modifiable, risk of sudden death (sudden unexpected death in epilepsy, SUDEP). Explaining risks of epilepsy, including SUDEP, should

27.49 UK driving regulations

The physician's prime duty is to ensure the patient is aware of the legal obligation to inform the driving authority.

Private use

Single seizure

- Cease driving for 6 months; a longer period may be required if risk of recurrence is high

Epilepsy (i.e. more than one seizure over the age of 5 years)

- Cease driving immediately
- Licence restored when patient is seizure-free for 1 year, *or* an initial sleep seizure is followed by exclusively sleep seizures for 1 year, *or* mixed awake and sleep seizures are followed by 3 years of exclusively sleep seizures
- Licence will require renewal every 3 years thereafter until patient is seizure-free for 10 years

Withdrawal of antiseizure medications

- Cease driving during withdrawal period and for 6 months thereafter

Vocational drivers (heavy goods and public service vehicles)

- No licence permitted if any seizure has occurred after the age of 5 years until patient is off medication and seizure-free for more than 10 years, and has no potentially epileptogenic brain lesion

27.50 Guidelines for antiseizure medication therapy*

- Start with one first-line drug (see Box 27.51)
- Start at a low dose; gradually increase dose until effective control of seizures is achieved or side-effects develop
- Optimise adherence (use minimum number of doses per day)
- If first drug fails (seizures continue or side-effects develop), start second first-line drug, followed if possible by gradual withdrawal of first
- If second drug fails (seizures continue or side-effects develop), start second-line drug in combination with the preferred baseline drug at maximum tolerated dose (beware interactions)
- If this combination fails (seizures continue or side-effects develop), replace second-line drug with alternative second-line drug
- If this combination fails, check adherence and reconsider diagnosis. (Are events seizures? Occult lesion? Treatment adherence/alcohol/drugs confounding response?)
- Consider alternative, non-drug treatments (e.g. epilepsy surgery, vagal nerve stimulation)
- Use minimum number of drugs in combination at any one time

*See Scottish Intercollegiate Guidelines Network SIGN 143 – Diagnosis and management of epilepsy in adults (May 2015).

27.51 Guidelines for choice of antiseizure medication[1]

Epilepsy type	First-line	Second-line	Third-line
Focal onset and/or secondary GTCS	Lamotrigine Levetiracetam	Carbamazepine Oxcarbazepine Zonisamide	Discuss with local epilepsy specialist
GTCS[2]	Lamotrigine Levetiracetam Sodium valproate (note safety measures and precautionary advice) If the first choice of treatment is unsuccessful, try another one of the treatments above as monotherapy or add-on treatment	Perampanel Topiramate (note safety measures and precautionary advice)	Discuss with local epilepsy specialist
Absence[2]	Ethosuximide	Lamotrigine Levetiracetam Sodium valproate (note safety measures and precautionary advice) If the first choice of treatment is unsuccessful, try another one of the treatments above as monotherapy or add-on treatment. If that is unsuccessful, try the third option as monotherapy or add-on treatment	Discuss with local epilepsy specialist
Myoclonic[2]	Levetiracetam Sodium valproate (note safety measures and precautionary advice) If the first choice is unsuccessful, try the other as monotherapy or add-on treatment	Brivaracetam Clobazam Clonazepam Lamotrigine Phenobarbital Piracetam Topiramate (note safety measures and precautionary advice) Zonisamide	Discuss with local epilepsy specialist

[1] See NICE Guideline NG 217: Epilepsies in children, young people and adults, updated 30 January 2025.

[2] Genetic generalised epilepsies.

N.B. Use as few drugs as possible at the lowest possible dose. Avoid sodium valproate and topiramate in women of childbearing age/potential unless benefit outweighs risk. Consult local medicine regulator regarding use in men.

(GTCS = generalised tonic–clonic seizure)

be done with care and sensitivity, and with the aim of motivating the patient to adapt habits and lifestyle to optimise epilepsy control and minimise risks of serious complications.

Antiseizure medications

Antiseizure medications (ASMs) should be considered where risk of seizure recurrence is high. A diagnosis of two or more seizures is justification enough but a prolonged inter-seizure interval may deter some patients and physicians. Treatment decisions should always be shared with the patient, to enhance adherence. A wide range of drugs is available. These agents either increase inhibitory neurotransmission in the brain or alter neuronal sodium channels to prevent abnormally rapid transmission of impulses. In the majority of patients, full control is achieved with a single drug. Dose regimens should be kept as simple as possible. Guidelines are listed in Box 27.50. For focal epilepsies, one large study suggests that lamotrigine is the best-tolerated monotherapy, which, alongside its favourable adverse-effect profile and relative lack of pharmacokinetic interactions, makes it a good first-line drug, although caution must be exercised with oral contraceptive use. Unclassified or genetic generalised epilepsies respond best to valproate, although the severe reproductive toxicities of valproate in women (and to a lesser extent in men) mean that alternative effective ASMs such as lamotrigine or levetiracetam should be considered in those of reproductive age. National regulatory and clinical guidelines should guide this decision. The initial choice should be an established first-line drug (Box 27.51), with more recently introduced drugs as second choice.

Monitoring therapy

Some practitioners confuse epilepsy care with serum level monitoring. The newer drugs have much more predictable pharmacokinetics than the older ones and the only indication for measuring serum levels is if there is doubt about adherence. Blood levels need to be interpreted carefully and dose changes made to treat the patient rather than to bring a serum level into the 'therapeutic range'. Some centres advocate serum level monitoring during pregnancy (notably with lamotrigine) but the evidence of benefit for this is not strong.

Epilepsy surgery

Some patients with drug-resistant epilepsy benefit from surgical resection of epileptogenic brain tissue. Less invasive treatments, including vagal nerve stimulation or deep brain stimulation, may also be helpful in some patients. All those who continue to experience seizures despite appropriate drug treatment should be considered for surgical treatment. Planning such interventions requires intensive specialist assessment and investigation to identify the site of seizure onset and the dispensability of any target areas for resection, i.e. whether the area of brain involved is necessary for a critical function such as vision or motor function.

Withdrawing antiseizure medication

Withdrawal of medication may be considered after a patient has been seizure-free for more than 2 years. Childhood-onset epilepsy, particularly classical absence seizures, carries the best prognosis for successful drug withdrawal. Other epilepsy syndromes, such as juvenile myoclonic epilepsy, have a marked tendency to recur after drug withdrawal.

Focal epilepsies that begin in adult life are also likely to recur, especially if there is an identified structural lesion. Overall, the recurrence rate after drug withdrawal depends on the individual's epilepsy history. An individualised estimate may be gained from the SIGN guideline tables (see 'Further information').

Patients should be advised of the risks of recurrence, to allow them to decide whether or not they wish to withdraw. If undertaken, withdrawal should be done slowly, reducing the drug dose gradually over weeks or months. Withdrawal may necessitate precautions around driving or occupation (see Box 27.49).

Contraception

Some ASMs induce hepatic enzymes that metabolise synthetic hormones, increasing the risk of contraceptive failure. This is most marked with carbamazepine, phenytoin and barbiturates, but clinically significant effects can be seen with lamotrigine and topiramate. If the ASM cannot be changed, this can be overcome by giving higher-dose preparations of the oral contraceptive. Sodium valproate and levetiracetam have no interaction with hormonal contraception.

Pregnancy and reproduction

Epilepsy presents specific management problems during pregnancy (Box 27.52). There is usually concern about the risks of teratogenesis associated with ASMs, which must be balanced against the benefits of these drugs. It is important to recognise proportionate risks: background risk of severe fetal malformation in the general population is around 2%–3%, while the ASM most associated with teratogenesis is sodium valproate, which, at high dose, increases the risk to up to 10%. Long-term observational studies show that most of the commonly used ASMs can be given safely in pregnancy, although the risk of congenital abnormalities in the fetus is dependent on the type, number and dose of ASMs.

27.52 Epilepsy in pregnancy

- **Provision of pre-conception counselling is best practice**: start folic acid (5 mg daily for 2 months) before conception to reduce the risk of fetal malformations.
- **Fetal malformation**: risk is minimised if a single drug is used.
  Carbamazepine and lamotrigine have the lowest incidence of major fetal malformations.
  The risk with sodium valproate is particularly high (see text) and should be carefully balanced against its benefits. Teratogenic risk with topiramate is also very high. Many countries have 'pregnancy prevention programmes' in place for both drugs and national medicines regulations should be followed.
  Levetiracetam may be safe but avoid other newer drugs if possible.
- **Learning difficulties in children**: IQ may be lower when children are exposed to valproate in utero and the risk of neurodevelopmental disorders is very high (up to 30%–40%), so its use should always be considered carefully.
- **Haemorrhagic disease of the newborn**: enzyme-inducing antiseizure medications increase risk. Give IM vitamin K (1 mg) to the infant at birth.
- **Increased frequency of seizures**: where breakthrough seizures occur, monitor antiseizure medication levels and adjust the dose regimen accordingly.
- **Pharmacokinetic effects of pregnancy**: carbamazepine levels may fall in the third trimester. Lamotrigine and levetiracetam levels may fall early in pregnancy. Some advocate monitoring of levels.

Over the past decade medicines regulatory agencies have strengthened their warnings surrounding the risk of birth defects and developmental disorders in children born to women who take valproate during pregnancy. In the UK it has been emphasised that if valproate is taken during pregnancy, up to 4 in 10 babies are at risk of neurodevelopmental disorders, in addition to the 1 in 10 who are at risk of birth defects. Consequently, in European countries, valproate must no longer be used in any woman or girl able to have children, unless she has a pregnancy prevention programme in place. Valproate is also associated with a spectrum of reproductive toxicities in men, including effects on spermatogenesis, a rare risk of infertility and increasing concerns about risks of neurodevelopmental disorders in children born to fathers exposed to valproate. We recommend consulting medicines regulatory agency advice before prescribing valproate.

Pre-conception treatment with folic acid (5 mg daily), along with use of the smallest effective doses of as few ASMs as possible, may reduce the risk of fetal abnormalities. The risks of abrupt ASM withdrawal to the mother should be stressed.

Seizures may become more frequent during pregnancy, particularly if pharmacokinetic changes decrease serum levels of ASMs (see Box 27.52).

Menstrual irregularities and reduced fertility are more common in women with epilepsy, and are also increased by sodium valproate. Patients with epilepsy are at greater risk of osteoporosis, apparently independently of the drug used. Some centres advocate vitamin D supplementation in any patient with epilepsy, but the higher female risk of osteoporosis makes this most important in women. Oral contraception can interact with individual ASMs (see Box 27.52).

Prognosis

The outcome of newly diagnosed epilepsy is generally good. Overall, generalised epilepsies and generalised seizures are more readily controlled than focal seizures. The presence of a structural lesion reduces the chances of freedom from seizures. The overall prognosis for epilepsy is shown in Box 27.48. Problems that epilepsy poses in older adults and in adolescents are summarised in Boxes 27.53 and 27.54, respectively.

Status epilepticus

Presentation and management are described on page 1168. While generalised status epilepticus is most easily recognised, non-convulsive

27.53 Epilepsy in old age

- **Incidence and prevalence**: late-onset epilepsy is very common and the annual incidence in those over 60 years is rising.
- **Fits and faints**: the features that usually differentiate these may be less definitive than in younger patients.
- **Non-convulsive status epilepticus**: can present as delirium in old age.
- **Cerebrovascular disease**: the underlying cause of seizures in 30%–50% of patients over the age of 50 years. A seizure may occur with an overt stroke or with occult vascular disease.
- **Neurogenerative disease** or dementia: should be considered when epilepsy presents in old age.
- **Antiseizure medication regimens**: keep as simple as possible and take care to avoid interactions with other drugs being prescribed.
- **Carbamazepine-induced hyponatraemia**: increases significantly with age; this is particularly important in patients on diuretics or those with heart failure.
- **Withdrawal of antiepileptic therapy**: drug withdrawal should be attempted only where benefits exceed risk of harm from seizures.

status may be less dramatic and less easily diagnosed. It may cause only altered awareness, delirium or wandering with automatisms. In an intensive care unit setting, EEG monitoring is essential to ensure that diagnosis and treatment are optimised.

Dissociative non-epileptic seizures (‘dissociative attacks’)

The difficulty with nomenclature is discussed on page 1997. Patients may present with attacks that resemble epileptic seizures but are caused by dissociative phenomena (p. 1183) and have no abnormal EEG discharges. Such attacks may be very prolonged, sometimes mimicking status epilepticus. Epileptic and dissociative non-epileptic attacks may coexist, and time and effort are needed to clarify the relative contribution of each, allowing more accurate and comprehensive treatment.

Dissociative non-epileptic seizures may be accompanied by dramatic flailing of the limbs and arching of the back, with side-to-side head movements and vocalising. Cyanosis and severe biting of the tongue are rare but incontinence can occur. Distress and crying are common following non-epileptic attacks. The distinction between epileptic attacks originating in the frontal lobes and non-epileptic attacks may be especially difficult, and may require videotelemetry with prolonged EEG recordings. Dissociative non-epileptic attacks are three times more common in women than in men. Patients and carers may need reassurance that hospital admission is not required for every attack. Prevention often requires psychotherapeutic interventions rather than drug therapy, though many patients benefit from identifying the symptoms or sensations they experience at the onset and exploring techniques to distract themselves such as counting, calculating or some other task that requires attention and concentration.

27.54 Epilepsy in adolescence

- **Effect on school/education**: seizures, antiseizure medications (ASMs) and psychological complications of epilepsy may hamper education. Fear may make some educational institutions unduly restrictive.
- **Effect on family relationships**: parents may adopt a protective role, which can lead to epilepsy (and ASMs) becoming a point of assertion and rebellion.
- **Effect on career choice**: epilepsy may exclude or restrict employment in the emergency services and armed forces.
- **Alcohol**: may affect sleep pattern; excess may be associated with poor ASM adherence.
- **Illicit drugs**: may affect seizure threshold and be associated with poor ASM adherence.
- **Sleep disturbance**: may be worsened by social activities and computer games.
- **Oral contraception**: interactions with ASM can occur. Use may not always be disclosed to parents.

Vestibular disorders

Vertigo is the typical symptom caused by vestibular dysfunction, and most patients with vertigo have acute vestibular failure, benign paroxysmal positional vertigo or Ménière disease. Central (brain) causes of vertigo are rare by comparison, with the exception of migraine.

Acute vestibular failure

Although commonly called ‘labyrinthitis’ or ‘vestibular neuronitis’, acute vestibular failure is a more accurate term, as most cases are idiopathic. It usually presents as isolated severe vertigo with vomiting and unsteadiness. It begins abruptly, often on waking, and many patients are initially bed-bound. The vertigo settles within a few days, though head movement may continue to provoke transient symptoms (positional vertigo) for some time. During the acute attack, nystagmus will be present for a few days.

Cinnarizine, prochlorperazine or betahistine provide symptomatic relief but should not be used long term, as this may delay recovery. A small proportion of patients fail to recover fully and complain of ongoing imbalance and dysequilibrium rather than vertigo; vestibular rehabilitation by a physiotherapist may help.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is due to the presence of otolithic debris from the saccule or utricle affecting the free flow of endolymph in the semicircular canals (cupulolithiasis). It may follow minor head injury but typically is spontaneous. The history is diagnostic, with transient (seconds) vertigo precipitated by movement (typically, rolling over in bed or getting into or out of bed). Although it is benign, and usually self-limiting after weeks or months, patients are often alarmed by the symptoms. The diagnosis can be confirmed by the ‘Hallpike manoeuvre’ to demonstrate positional nystagmus (Fig. 27.39). Treatment comprises explanation and reassurance, along with positioning procedures

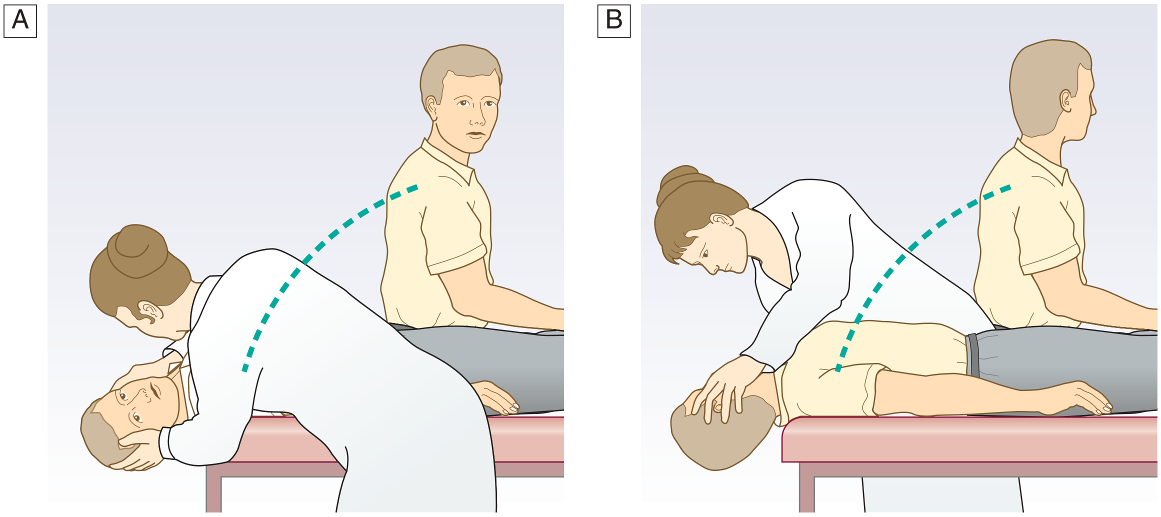

Fig. 27.39 The Hallpike manoeuvre for diagnosis of benign paroxysmal positional vertigo (BPPV). Patients are asked to keep their eyes open and look at the examiner as their head is swung briskly backwards through 120° to overhang the edge of the couch. **A** Perform first with the right ear down. **B** Perform next with the left ear down. The examiner looks for nystagmus (usually accompanied by vertigo). In BPPV, the nystagmus typically occurs in A or B only and is torsional, the fast phase beating towards the lower ear. Its onset is usually delayed a few seconds and it lasts 10–20 seconds. As the patient is returned to the upright position, transient nystagmus may occur in the opposite direction. Both nystagmus and vertigo typically decrease (fatigue) on repeat testing.

designed to return otolithic debris from the semicircular canal to saccule or utricle (such as the Epley manoeuvre) and/or to re-educate the brain to cope with the inappropriate signals from the labyrinth (such as Cawthorne–Cooksey exercises: see 'Further information').

Ménière disease

This is due to an abnormality of the endolymph that causes episodes of vertigo accompanied by tinnitus and fullness in the ear, each attack typically lasting a few hours. Over the years, patients may develop progressive deafness (typically low-tone on audiometry). Examination is typically normal in between attacks. The diagnosis is clinical, supported by abnormal audiometry. Ménière disease is idiopathic, but a similar syndrome may be caused by middle ear trauma or infection. Imaging may be indicated to exclude other focal brainstem or cerebellopontine angle pathology but will be normal in Ménière disease. Management includes a low-salt diet, vestibular sedatives for acute attacks (e.g. cinnarizine or prochlorperazine), and occasionally surgery to increase endolymphatic drainage from the vestibular system. Migraine may also cause episodic vertigo and can be confused with Ménière disease, although usually other migrainous features will appear in the history.

Disorders of sleep

Sleep disturbances include too much sleep (hypersomnolence or excessive daytime sleepiness), insufficient or poor-quality sleep (insomnia) and abnormal behaviour during sleep (parasomnias). Insomnia is usually caused by psychological or psychiatric disorders, shift work and other environmental causes, pain and so on, and will not be discussed further. Many symptoms and disorders may affect sleep and sleep quality (e.g. pain, depression/anxiety, parkinsonism).

Excessive daytime sleepiness (hypersomnolence)

There are primary and secondary causes (Box 27.55). The most common causes are impaired sleep due to lifestyle issues or sleep-disordered breathing. Sleepiness may be measured using the Epworth sleepiness scale (see Box 17.87). Most causes will be identified by a detailed history from the patient and their bed partner, and a 2-week sleep diary.

Narcolepsy

This has a prevalence of about 1 in 2000, with peak onset in adolescence and early middle age. The key symptom is sudden, irresistible 'sleep attacks', often in inappropriate circumstances such as while eating or talking. Other characteristic features help distinguish this from excessive daytime sleepiness (Box 27.56). Symptoms may be due to loss of hypocretin-secreting hypothalamic neurons. Diagnosis requires sleep study with sleep latency testing (demonstrating rapid onset of REM sleep). Narcolepsy may respond to stimulants such as modafinil but more severe cases may require sodium oxybate, dexamfetamine, methylphenidate or a selective serotonin reuptake inhibitor (SSRI). Cataplexy can be debilitating and can respond to sodium oxybate or to antidepressants, such as clomipramine or venlafaxine.

27.55 Causes of hypersomnolence

Primary causes

- Narcolepsy
- Idiopathic hypersomnolence
- Brain injury

Secondary causes (due to poor-quality sleep)

- Obstructive sleep apnoea
- Pain
- Restless legs/periodic limb movements of sleep
- Parkinsonism and other neurodegenerative diseases
- Depression/anxiety
- Medication
- Environmental factors (noise, temperature etc.)

Parasomnias

Parasomnias are abnormal motor behaviours that occur around sleep. They may arise in either REM or non-REM sleep, with characteristic features and timing. Non-REM parasomnias tend to occur early in sleep. Parasomnias should be distinguished from other motor disturbances (such as periodic limb movements, hypnic jerks or sleep talking) and sleep-onset epileptic seizures. History from a sleeping partner or other witness is essential.

Non-REM parasomnias

These are due to incomplete arousal from non-REM sleep and manifest as night terrors, sleep walking and confusional arousals (sleep drunkenness). They typically occur within an hour or two of sleep onset, are common in children and usually of no pathological significance. Rarely, they persist into adulthood and may become increasingly complex, including dressing, moving objects, eating, drinking or even acts of violence. Patients have little or no recollection of the episodes, even though they appear 'awake'. The episodes may be triggered by alcohol or unfamiliar sleeping situations and can be familial. Treatment is usually not required but clonazepam can be used.

REM sleep behaviour disorder

In REM sleep behaviour disorder (RBD), patients 'act out' their dreams during REM sleep, due to failure of the usual muscle atonia. Sleep partners provide typical histories of patients 'fighting' or 'struggling' in their sleep, sometimes causing injury to themselves or to their partner. They are easily roused from this state, with recollection of their dream, unlike in non-REM states. RBD is more common in men and may be an early symptom of neurodegenerative diseases such as alpha synucleinopathies, perhaps preceding more typical symptoms of these conditions by years. Polysomnography will confirm absence of atonia during REM sleep. Clonazepam is the most successful treatment.

Restless legs syndrome

Restless legs syndrome (RLS) is common, with a prevalence of up to 10%, but many patients never seek medical attention. It is characterised by unpleasant leg (rarely, arm) sensations that are eased by movement (motor restlessness); the diagnosis is clinical (Box 27.57). It has a strong familial tendency and can present with daytime somnolence due to poor sleep. It is usually idiopathic but may be associated with iron deficiency, pregnancy, peripheral neuropathy, Parkinson disease or uraemia. It should be distinguished from akathisia, the daytime motor restlessness that is an adverse effect of antipsychotic drugs.

27.56 Narcolepsy symptoms

Sleep attacks

- Brief, frequent and unlike normal somnolence

Cataplexy

- Sudden loss of muscle tone triggered by surprise, laughter, strong emotion etc.

Hypnagogic or hypnopompic hallucinations

- Frightening hallucinations experienced during sleep onset or waking due to intrusion of REM sleep during wakefulness (can occur in normal people)

Sleep paralysis

- Brief paralysis on waking (can occur in normal people)

27.57 Diagnostic criteria for restless legs syndrome

A need to move the legs, usually accompanied or caused by uncomfortable, unpleasant sensations in the legs, with the following features:

- only present or worse during periods of rest or inactivity, such as lying or sitting
- partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues
- generally worse or occurs only in the evening or night.

Treatment, if required, is with gabapentanoids as first line, dopaminergic drugs (dopamine agonists or levodopa) or benzodiazepines. Codeine or opioids are used for refractory RLS. Patients prescribed dopamine agonists should be counselled about risks of impulse control disorders including gambling, excessive shopping, hypersexuality and compulsions and regularly monitored for these side-effects. Serum ferritin should be maintained above 75 μg/L.

Periodic limb movements in sleep

Unlike RLS, periodic limb movements in sleep (PLMS) only occur during sleep and cause repetitive flexion movements of the limbs, usually in the early (non-REM) stages of sleep. Although patients are unaware of the symptoms, they may disrupt sleep quality and often disturb partners. The pathological significance of PLMS is uncertain and it often occurs in normal health. There is an overlap with RLS. Treatment is most successful with clonazepam or dopaminergic drugs.

Neuro-inflammatory diseases

Multiple sclerosis

Multiple sclerosis (MS) is an important treatable cause of long-term disability in adults. The annual incidence is around 7 per 100 000, while the lifetime risk of developing MS is about 1 in 400. The incidence of MS is higher in Northern Europeans and the disease is about twice as common in females.

Pathophysiology

There is evidence that both genetic and environmental factors play a causative role. The prevalence of MS is low near the equator and increases in the temperate zones of both hemispheres. People retain the risk of developing the disease in the zone in which they grew up, indicating that environmental exposures during growth and development are important. Prevalence also correlates with environmental factors, such as sunlight exposure, vitamin D and exposure to Epstein–Barr virus (EBV), although causative mechanisms remain unclear. Genetic factors are also relevant; the risk of familial occurrence in MS is 15%, with highest risk in first-degree relatives (age-adjusted risk 4%–5% for siblings and 2%–3% for parents or offspring). Large genome-wide association studies (GWAS) of MS implicate the modest influence of hundreds of genes, in particular those with an immunological function, and there is overlap with other immune diseases. An autoimmune cause of multiple sclerosis is therefore supported by genetic studies, a prominent role of immune cells in disease pathogenesis and efficacy of multiple immune therapies.

Initial CNS inflammation in MS involves entry of lymphocytes across the blood–brain barrier, which can be inhibited by the monoclonal antibody natalizumab, which bind $\alpha4\beta1$-integrin. These cells proliferate in perivascular lesions and the resulting inflammatory cascade releases cytokines and initiates destruction of the oligodendrocyte–myelin unit. Histologically, the resultant lesion is a plaque of inflammatory demyelination, most commonly in the periventricular regions of the brain, the optic nerves and the spinal cord (Fig. 27.40), and also found in the cortex. After the acute attack, gliosis and repair by oligodendrocyte precursor cells follows, leaving a shrunken scar.

Much of the initial acute clinical deficit is caused by the effect of inflammation on transmission of the nervous impulse rather than structural disruption of myelin, and may explain the rapid recovery of some deficits. In the long term, accumulating myelin loss reduces the efficiency of impulse propagation or causes complete conduction block, contributing to sustained impairment of CNS functions. Inflammatory mediators released during the acute attack, and loss of structural and trophic support from myelinating cells, contribute to axonal damage, which is a feature of the latter stages of the disease and is an important substrate of disability in the later, progressive phase of MS (Fig. 27.41).

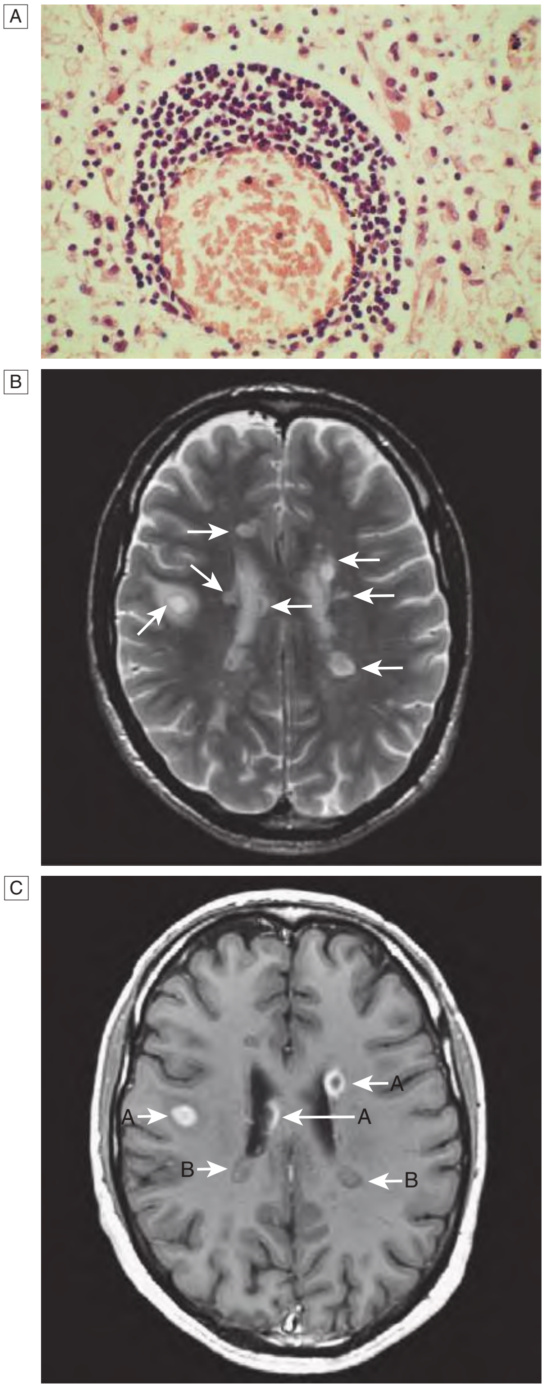

Fig. 27.40 Multiple sclerosis. A Photomicrograph from demyelinating plaque, showing perivascular cuffing of blood vessel by lymphocytes. B Brain magnetic resonance imaging in multiple sclerosis. Multiple high-signal lesions (arrows) seen particularly in the paraventricular region on T2 image. C In T1 image with gadolinium enhancement, recent lesions (A arrows) show enhancement, suggesting active inflammation (enhancement persists for 4 weeks); older lesions (B arrows) show no enhancement but low signal, suggesting gliosis.

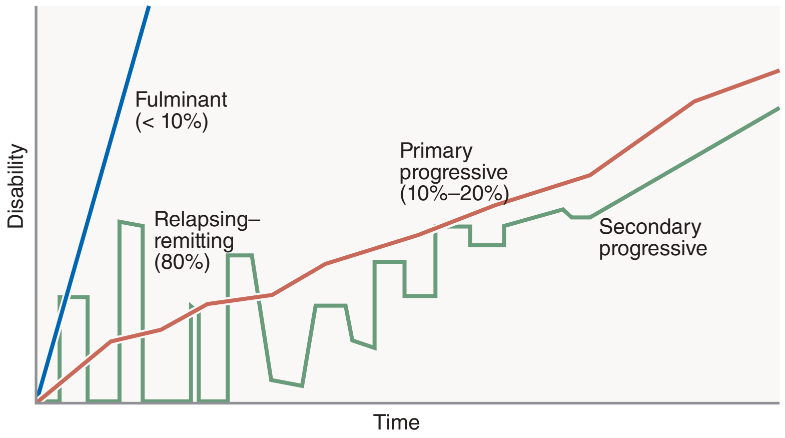

Fig. 27.41 **The progression of disability in fulminant, relapsing–remitting and progressive multiple sclerosis.** *Courtesy of Professor D.A.S. Compston.*

27.58 The McDonald criteria for the diagnosis of multiple sclerosis (MS) (2017)*

Number of clinical attacks	Number of lesions with objective clinical evidence	Additional evidence required to diagnose MS
≥ 2	≥ 2	None
≥ 2	1 (with reasonable historical evidence of a previous relapse)	None
≥ 2	1	Dissemination in space demonstrated by an additional clinical attack implicating a different CNS site or by MRI
1	≥ 2	Dissemination in time demonstrated by an additional clinical attack or by MRI or demonstration of CSF-specific oligoclonal bands
1	1	Dissemination in space demonstrated by an additional clinical attack implicating a different CNS site or by MRI *and* Dissemination in time demonstrated by an additional clinical attack or by MRI, or demonstration of CSF-specific oligoclonal bands

*The diagnostic criteria require reasonable exclusion of other possible causes for central nervous system inflammation.

27.59 Clinical features of multiple sclerosis

Common presentations of multiple sclerosis

- Optic neuritis
- Transverse myelitis
- Brainstem syndrome
- Cerebellar syndrome

Other symptoms and syndromes seen in MS

- Afferent pupillary defect and optic atrophy (previous optic neuritis)
- Lhermitte symptom (tingling in spine or limbs on neck flexion)
- Progressive paraparesis
- Partial Brown–Séquard syndrome (see Fig. 27.22)
- Internuclear ophthalmoplegia with ataxia
- Tremor
- Cognitive dysfunction
- Trigeminal neuralgia under the age of 50

Clinical features

The diagnosis of MS requires the demonstration of otherwise unexplained CNS lesions separated in time and space (Box 27.58); traditionally, this meant two or more clinical relapses affecting different parts of the nervous system, and the first ever episode is often referred to as a 'clinically isolated syndrome' (CIS). However, recent changes to diagnostic criteria mean that MS may be diagnosed after an isolated episode because MRI can identify clinically silent lesions of different ages, and the presence of unpaired oligoclonal bands in the CSF can strongly suggest the development of future events (see Box 27.58). As such, MS can be proactively diagnosed and treated compared to a decade ago. The peak age of onset of MS is the fourth decade; onset in childhood or after the age of 70 years is less common but can occur.

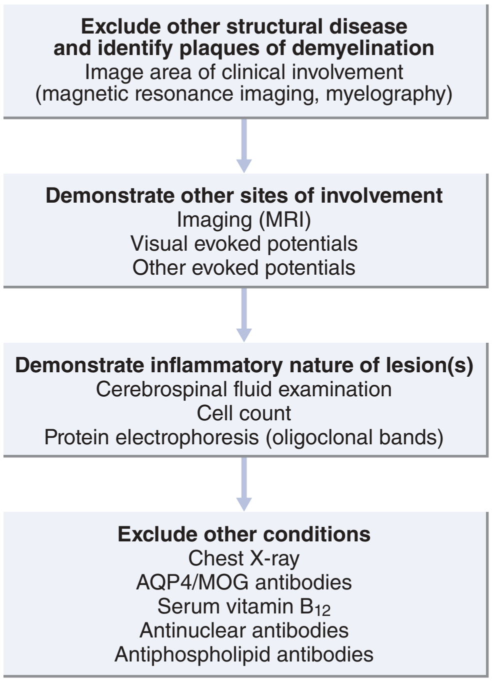
Symptoms and signs of MS usually evolve over days or weeks, resolving over weeks or months. About 85%–90% of patients have an initial relapsing and remitting clinical course with variable intervening recovery, although the majority will eventually enter a secondary progressive phase. Most of the rest follow a slowly progressive clinical course (so-called primary progressive MS). Aggressive variants of multiple sclerosis can occur, and this can include presentation with tumour-like lesions which may require biopsy for confirmation (see Fig. 27.41). The clinical course of multiple sclerosis is highly variable and difficult to predict. Frequent relapses with incomplete recovery indicate a poorer prognosis and the need for high efficacy therapy. Some milder cases have an interval of years or even decades between attacks.

There are a number of typical clinical symptoms and syndromes suggestive of MS, occurring either at presentation or during the course of the illness (Box 27.59). The physical signs observed in MS are determined by the anatomical site of inflammation. Combined spinal cord and brainstem signs are common, although evidence of previous optic neuritis may be found in the form of an afferent pupillary deficit. Cognitive symptoms of MS are underappreciated and can be significant, particularly in the later stages of the disease.

The prognosis for patients with MS is difficult to predict with confidence, especially early in the disease. Those with untreated relapsing and remitting MS experience, on average, 1–2 relapses every 2 years, although this may decline with time. Prognosis is better for patients with optic neuritis and only sensory relapses. Overall, about one-third of patients are disabled to the point of needing help with walking after 10 years, and this proportion rises to about half after 15 years. It would appear likely (though this is as yet unproven) that disease-modifying drugs will have an effect on long-term disability.

Investigations

There is no single diagnostic test that is definitive for MS and the results of investigation need to be combined with the clinical picture in order to make a diagnosis; MRI is the most important investigation (Fig. 27.42).



Exclude other structural disease and identify plaques of demyelination
Image area of clinical involvement
(magnetic resonance imaging, myelography)
Demonstrate other sites of involvement
Imaging (MRI)
Visual evoked potentials
Other evoked potentials
Demonstrate inflammatory nature of lesion(s)
Cerebrospinal fluid examination
Cell count
Protein electrophoresis (oligoclonal bands)
Exclude other conditions
Chest X-ray
AQP4/MOG antibodies
Serum vitamin B12
Antinuclear antibodies
Antiphospholipid antibodies

Fig. 27.42 Investigations in a patient suspected of having multiple sclerosis. (AQP4 = aquaporin-4; MOG = myelin oligodendrocyte glycoprotein)

MS mimics should be excluded (see below). Following the first clinical event, investigations help confirm the disseminated nature of the disease. MRI is the most sensitive technique for imaging lesions in brain and spinal cord (Fig. 27.43) and for excluding other causes that have provoked the neurological deficit. MS lesions often have an oval appearance, and lesions which have developed in the past couple of months usually take up contrast around the lesion rim. Typical MRI lesion locations include the periventricular region, juxtacortical, infratentorial regions and spinal cord. Spinal cord lesions in MS are typically short and are asymmetric (see Fig. 27.43). Longer spinal cord lesions, over 3 vertebral bodies in length, should raise the possibility of neuromyelitis optica, an antibody-mediated neuroinflammatory disease which is associated with antibodies against aquaporin-4 and myelin oligodendrocyte glycoprotein (MOG). Antibodies against MOG are increasingly recognised to cause a distinct MS-like inflammatory condition called MOG antibody-associated disease (MOGAD), which can cause acute brain inflammation in children and opticospinal inflammation in adults. Cell-based assays are particularly important to detect this antibody. In older age groups, MRI appearances in MS may be confused with those of small-vessel disease, and non-specific white matter lesions can be seen in common conditions such as migraine. Therefore, careful and experienced evaluation of brain and spinal cord imaging is important for accurate diagnosis.

In MS, the CSF typically has a normal white cell count and protein, although may show a small lymphocytic pleocytosis in active disease. CSF can be used to identify intrathecal synthesis of immunoglobulins in MS. Oligoclonal bands are found in the CSF but not the blood in about 90% of patients. The presence of these bands can help facilitate a more rapid diagnosis of MS in individuals who have had a single clinical event, since they suggest a more chronic neuroinflammatory process. Oligoclonal bands are not specific for MS and denote only intrathecal inflammation, provided they are unique for the CSF. These can appear in other disorders, which should be excluded by examination and investigation. It is important to exclude other potentially treatable conditions, such as infection, vitamin B_{12} deficiency and spinal cord compression.

Management

The management of MS involves (1) disease modifying therapies and (2) symptomatic approaches.

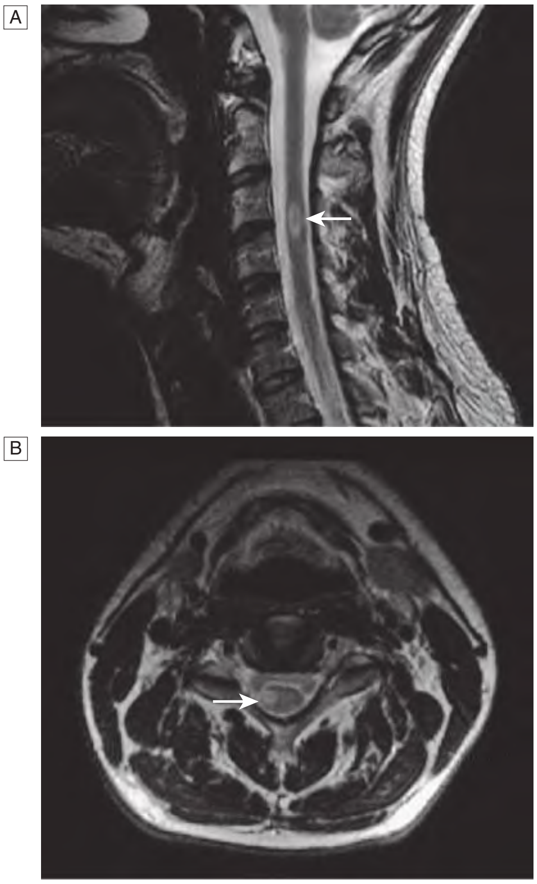


Fig. 27.43 Multiple sclerosis. Demyelinating lesion in cervical spinal cord, high-signal T2 images (arrows). **A** Sagittal plane. **B** Axial plane.

Disease-modifying treatment (DMT)

The past two decades have seen enormous progress in the treatment of multiple sclerosis, in particular the treatment of early MS. There is a broad spectrum of immunotherapies for the treatment of MS, with > 10 drugs approved in Europe and the United States. These drugs are most efficacious in the relapsing–remitting phase of disease, and early diagnosis and treatment is increasingly viewed as important in improving long-term outcomes. All DMTs reduce relapse frequency and higher efficacy drugs, for example B cell–depleting monoclonal antibodies, reduce the development of disability. Recently, immunotherapies such as siponimod and ocrelizumab have also been approved to prevent disability in progressive forms of MS, although only where active inflammation can be demonstrated. In general, drugs with higher efficacy are associated with more serious side-effects, and clinical trials are under way to determine the optimum level of immune treatment early in the course of MS (Box 27.60). Careful selection and counselling of patients are necessary, and these drugs should be supervised by teams experienced in their use, as recommended in national guidelines. Some DMTs can be used during pregnancy, but MS specialist advice should be sought.

Smoking, poor diet and obesity are risk factors for disease progression in MS and should be addressed as early as possible.

The acute relapse

In a disabling relapse of MS, pulses of high-dose glucocorticoid, given either intravenously or orally over 3–5 days, will shorten the duration of the acute episode, but will not affect long-term recovery. Plasma exchange is reserved for disabling relapses which do not respond to steroids. If a patient develops a new neurological deficit whilst on a DMT, consideration should also be given to possible neurological side-effects of the drug (e.g. visual loss due to fingolimod-associated macular oedema, cognitive

27.60 Disease-modifying treatments in relapsing-remitting multiple sclerosis

Treatment	Route of administration/dosing	Comment
High-efficacy biologic therapy: average relapse rate reduction > 50%		
Ocrelizumab	Intravenous infusion every 6 months	Associated with infusion reactions, increased infection risk and hypogammaglobulinaemia. Also used in treatment of some cases of primary progressive MS. Rituximab is also widely used in some countries with strong RCT evidence
Ofatumumab	Subcutaneous injection every month	Similar efficacy and safety profile to ocrelizumab
Natalizumab	4-weekly intravenous infusion	Risk of PML in individuals who have evidence of JC virus infection
Alemtuzumab	Intravenous infusion over two courses separated by 12 months; 5-day infusion initially, second course 3 days	Cytokine release syndrome and infusion reactions. 30% develop secondary autoimmunity, mainly affecting thyroid
Moderate efficacy immunotherapy: average relapse rate reduction 30%–50%		
Fingolimod	Daily oral	More effective than interferon. First dose bradycardia, increased susceptibility to infections, macular oedema. Other drugs from this class (e.g. siponimod) are licensed for the treatment of secondary progressive MS
Cladribine	Pulsed oral treatment	Risk of lymphopenia and infections. Some concern about longer-term cancer risk
Dimethyl fumarate	Daily oral	May cause flushing and gastrointestinal disturbance. Small risk of PML
Lower efficacy immunotherapy: average relapse rate reduction 30%		
Glatiramer acetate	Alternate-day subcutaneous injection	Similar efficacy to interferon-beta
Teriflunomide	Daily oral	May cause diarrhoea, alopecia, hepatotoxicity and teratogenicity
Interferon-beta	Alternate-day or weekly intramuscular or subcutaneous injection	In widespread use for reducing relapse rate

(JC virus = human polyoma virus 2; PML = progressive multifocal leucoencephalopathy; RCT = randomised controlled trial)

27.61 Treatment of complications in multiple sclerosis

Dysaesthesia and pain

- Carbamazepine
- Gabapentin
- Duloxetine
- Amitriptyline

Walking speed

- Fampridine

Bladder symptoms

- See Box 27.23

Erectile dysfunction

- Sildenafil 50–100 mg/day

Tadalafil

Spasticity

- Physiotherapy
- Baclofen (usually oral)
- Dantrolene
- Gabapentin
- Cannabinoids
- Tizanidine
- Intrathecal baclofen
- Local (intramuscular) injection of botulinum toxin
- Chemical neuronectomy

27.62 Multiple sclerosis in pregnancy

- **Counselling**: provision of pre-conception counselling is best practice
- **Relapse risk**: slight reduction in relapse rate during pregnancy, but increased risk of postpartum relapse
- **Disease-modifying drugs**: some DMTs can be continued during pregnancy following assessment of risk–benefit. Specialist advice is recommended in all cases
- **Breastfeeding**: Specialist advice should be sought since many DMTs are excreted in breastmilk

(DMT = disease-modifying treatment)

symptoms caused by natalizumab-associated progressive multifocal leucoencephalopathy).

Treatment of symptoms, complications and disability

Treatments for the complications of MS are summarised in Box 27.61. It is important to provide patients with a careful explanation of the nature of the disease and its outcome. Specialist nurses working in a multidisciplinary team of health-care professionals are of great value in managing the chronic phase of the disease. Input from physiotherapy and occupational therapy may improve functional capacity in those who become disabled, and guidance can be provided on the provision of aids at home. Bladder care is particularly important. Urgency and frequency can be treated pharmacologically (see Box 27.23), but this may lead to a degree of retention with an attendant risk of infection. Urinary retention can be managed initially by intermittent urinary catheterisation, but an in-dwelling catheter may become necessary. It is important to address sexual dysfunction, which can occur and is a frequent source of distress. Pregnancy does not increase the risk of progression of MS, but relapses may occur post-partum (Box 27.62).

Acute disseminated encephalomyelitis (ADEM)

This is an acute, often severe monophasic demyelinating condition in which areas of perivenous demyelination are widely disseminated throughout the brain and spinal cord. The illness may arise spontaneously but often occurs a week or so after a viral infection, especially measles or chickenpox, or following vaccination, suggesting that it is immunologically mediated.

Clinical features

Headache, vomiting, pyrexia, delirium and meningism may be presenting features, often with focal or multifocal brain and spinal cord signs. Seizures or coma may occur. A minority of patients who recover have further episodes.

Investigations

MRI shows multiple high-signal areas in a pattern similar to that of MS, although often with large confluent areas of abnormality. CSF may be normal or show an increase in protein and lymphocytes (occasionally $>100\times10^6$ cells/L). Oligoclonal bands may be found in the acute episode but, in contrast to MS, do not persist beyond clinical recovery. The clinical picture may be very similar to a first relapse of MS. ADEM in childhood is frequently associated with MOG antibodies.

Management

The prognosis for acute disseminated encephalomyelitis is generally good, although occasionally it may be fatal. Treatment with high-dose intravenous methylprednisolone, using the same regimen as for a relapse of MS, is recommended.

Transverse myelitis

Transverse myelitis is an acute, usually monophasic, demyelinating disorder affecting the spinal cord. It is sometimes thought to be post-infectious in origin. It occurs at any age and presents with a subacute paraparesis with a sensory level, accompanied by severe pain in the neck or back at the onset. MRI should distinguish this from an external lesion affecting the spinal cord. CSF examination shows cellular pleocytosis. Oligoclonal bands are usually absent. Treatment is with high-dose intravenous methylprednisolone. The outcome is variable: one-third have static deficit, one-third go on to develop MS and one-third recover with no subsequent relapse. Some clinical features may suggest a higher risk of MS after transverse myelitis.

Neuromyelitis optica

Neuromyelitis optica spectrum disorder (NMOSD, previously Devic disease) typically presents with severe optic neuritis or longitudinally extensive transverse myelitis. NMO can also cause severe vomiting or hiccups due to brainstem dysfunction. With cord presentations, spinal MRI scans show lesions that are typically longer than three spinal segments. The majority of cases are associated with an antibody against an astrocytic water channel, aquaporin-4. It is likely that this is a pathogenic antibody. The presence of aquaporin-4 antibodies is a strong predictor of future relapse. More recently it is recognised that some cases of NMOSD can be associated with myelin oligodendrocyte glycoprotein-associated MOG antibodies, although these patients might be less prone to severe relapse. A proportion of NMOSD are not associated with known antibodies. Brain lesions can be seen on MRI, but are less prominent than in MS and can develop in aquaporin-4-rich areas around the base of the fourth ventricle. Clinical deficits tend to recover less well than in MS, and the disease may be more aggressive with more frequent relapses. Treatment with glucocorticoids, oral immunosuppression and rituximab is often used. Recent clinical trials have suggested efficacy of B-cell depletion, IL-6 blockade and complement inhibition (Fig. 27.44).

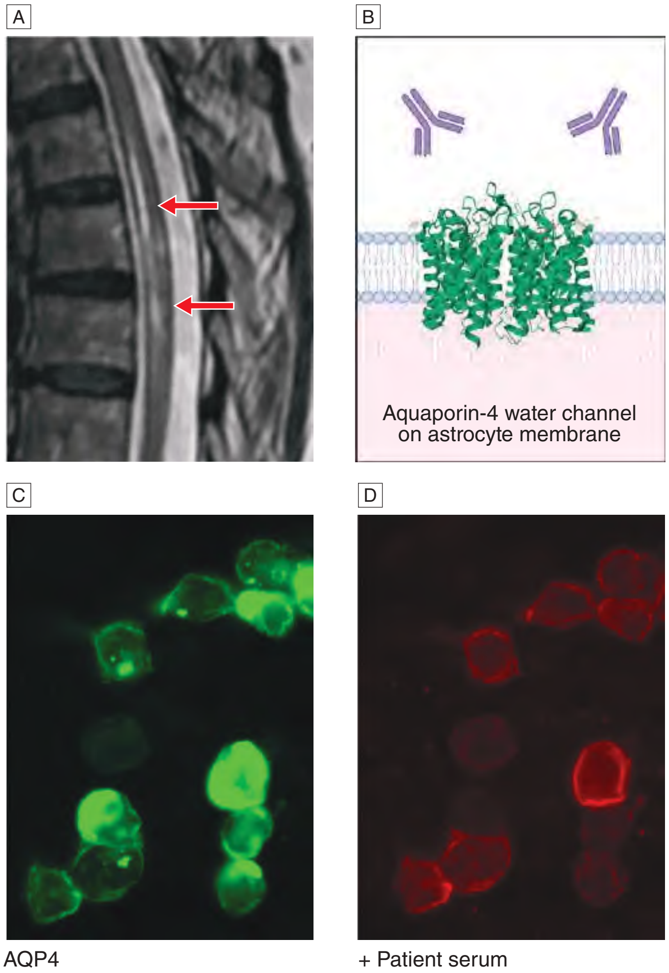

Fig. 27.44 Neuromyelitis optica. NMOSD typically causes longitudinally extensive transverse myelitis, extending over three or more vertebral segments. **A** MRI scan of spinal cord (T2-weighted) shows long hyperintense lesion within the thoracic spinal cord (red arrows). **B** NMOSD is typically associated with antibodies against the astrocytic water channel aquaporin-4 (AQP4). **C** These antibodies can be detected by cell-based assays, where serum is added to cells transfected with AQP4 (green). **D** If antibodies are present in serum, these bind to the surface of the transfected cells (red). *(A) From Williams J, McGlasson S, Irani S, et al. Neuromyelitis optica in patients with increased interferon alpha concentrations. Lancet Neurol 2020;19(1):31–33. (D) Courtesy of Professor Sarosh Irani, University of Oxford.*

Autoimmune encephalitis

Autoimmune encephalitis (AE) is an immune-mediated brain disease which can occur at any age and presents with cognitive symptoms, behavioural change and seizures. AE can occasionally develop following a preceding infection and should be considered if there is an inflammatory deterioration following recovery from an initial brain infection. AE can present with distinct clinical syndromes and these are associated with specific autoantibodies directed against neuronal cell surface antigens. Limbic encephalitis presents with memory disturbance (and can mimic neurodegenerative dementia in older persons), emotional and behavioural disturbance and seizures, which can cause brief dystonic movements of the face and arm (facio-brachial dystonic seizures). MRI may show enhancement and inflammation in hippocampus and associated limbic structures, and there are often mild inflammatory changes in the CSF. There is a strong association with Lgi1 and CASPR2 antibodies.

AE can also be associated with NMDAR antibodies, and this syndrome typically presents with neuropsychiatric symptoms, movement disorders, autonomic dysfunction and seizures and often causes serious illness requiring intensive care admission. A subset of NMDAR encephalitis is associated with ovarian teratoma. Corticosteroids, immune globulin and plasma exchange are often used acutely. AE can relapse or follow a chronic course, and long-term immunosuppression with oral immunosuppressants, cyclophosphamide or rituximab may be needed.

Paraneoplastic neurological disorders

Neurological disease may occur with systemic malignant tumours in the absence of cerebral metastases. It is now recognised that, in the majority of these cases, antigen production in the body of the tumour leads to development of antibodies to parts of the CNS. Paraneoplastic conditions are increasingly recognised and the number of antibodies identified is also growing (Box 27.63). These syndromes are particularly associated with small-cell carcinoma of lung, ovarian tumours and lymphomas. Autoantibodies are found in the serum and/or CSF, and biopsy will show a lymphocytic infiltrate of the neural tissue affected.

Clinical features

Clinical presentations are summarised in Box 27.63. In most instances, the neurological condition progresses quite rapidly over a few months, preceding the malignant disease in around half of cases. The range of clinical patterns is so wide that paraneoplastic disease should be considered in the diagnosis of any unusual progressive neurological syndrome. The paraneoplastic disorders of the peripheral nervous system particularly affect the synaptic cleft (p. 1152).

Investigations and management

The presence of characteristic autoantibodies in the context of a suspicious clinical picture may be diagnostic. The causative tumour may be very small and therefore CT of the chest or abdomen or PET scanning

27.63 Paraneoplastic disorders of the nervous system

Clinical presentation	Associated tumour
Central nervous system	
Limbic encephalitis	SCLC, testicular, breast, thymoma, teratoma
Myelopathy	SCLC, thymoma, others
Stiff person syndrome	Breast, SCLC, thymoma, others
Cerebellar degeneration	Breast, ovarian, SCLC, lymphoma
Encephalomyelitis	SCLC, thymoma
Opsoclonus–myoclonus	Breast, ovarian, SCLC, neuroblastoma, testicular
Optic neuritis	SCLC
Peripheral nervous system	
Neuromyotonia	Thymoma, SCLC, others
Myasthenia gravis	Thymoma
Sensorimotor polyneuropathy	Lymphoma, SCLC, others
Lambert–Eaton syndrome	SCLC
Motor neuropathy	Lymphoma, SCLC, others
Sensory neuropathy	Lymphoma, SCLC, others
Polymyositis/dermatomyositis	Lung, breast

(SCLC = small cell lung cancer)

may be necessary to find it. These investigations should be pursued only when paraneoplastic disease has been proven, rather than when it is suspected. The CSF often shows an increased protein and lymphocyte count with oligoclonal bands.

Treatment is directed at the primary tumour. Occasionally, successful therapy of the tumour is associated with improvement of the paraneoplastic syndrome. Some improvement may occur following administration of intravenous immunoglobulin.

Neurodegenerative diseases

While MS is the most common cause of disability in young people in the UK, vascular and neurodegenerative diseases are increasingly important in later life. The neurodegenerative diseases are united in having a pathological process that leads to specific neuronal death, causing relentlessly progressive symptoms, with incidence rising with age. The causes are not yet known, although genetic influences are important. Alzheimer disease and Parkinson disease are the most common.

Movement disorders

Movement disorders present with a wide range of symptoms. They may be genetic or acquired, and the most important is Parkinson disease. Most movement disorders are categorised clinically, with few confirmatory investigations available other than for those with a known gene abnormality.

27.64 Causes of parkinsonism

Idiopathic Parkinson disease (at least 80% of parkinsonism)

Cerebrovascular disease

Drugs and toxins

- Antipsychotic drugs (older and 'atypical')
- Metoclopramide, prochlorperazine
- Tetrabenazine
- Sodium valproate
- Lithium
- Manganese
- MPTP

Other degenerative diseases

- Dementia with Lewy bodies
- Progressive supranuclear palsy
- Multiple system atrophy
- Corticobasal degeneration
- Alzheimer disease

Genetic

- Huntington disease
- Fragile X tremor ataxia syndrome
- Dopa-responsive dystonia
- Spinocerebellar ataxias (particularly SCA 3)
- Wilson disease

Anoxic brain injury

(MPTP = methyl-phenyl-tetrahydropyridine)

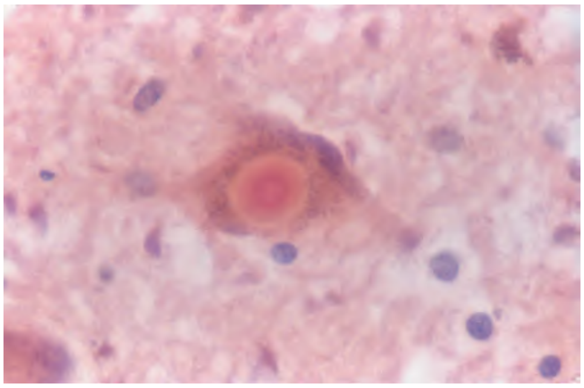

Fig. 27.45 Parkinson disease. High power (×400) view of substantia nigra of a patient with Parkinson disease showing classical Lewy body (haematoxylin and eosin). *Courtesy of Dr J. Xuereb.*

Idiopathic Parkinson disease

Parkinsonism is a clinical syndrome characterised primarily by bradykinesia, with associated increased tone (rigidity), tremor and loss of postural reflexes. There are many causes (Box 27.64) but the most common is Parkinson disease (PD). PD has an annual incidence of about 18/100 000 in the UK and a prevalence of about 180/100 000. Age has a critical influence on incidence and prevalence, the latter rising to 300–500/100 000 after 80 years of age. The global prevalence of PD (over 6 million in 2016) more than doubled between 1990 and 2016 with increases across all socio-demographic regions of the world, related mainly to increasing age and longer disease duration. Average age of onset is about 60 years and fewer than 5% of patients present under the age of 40. Genetic factors are increasingly recognised and several single genes causing parkinsonism have been identified. Monogenic Parkinson disease can be caused by pathogenic variants in *SNCA* (which encode alpha-synuclein), as well as *Parkin*, *PINK1, DJ-1* and many more, although overall monogenic disease accounts for a very small proportion of cases overall. Pathogenic variants in the *LRRK2* gene are the most frequent genetic cause of late-onset PD. Having a first-degree relative with PD confers a 2–3 times increased risk of developing the disorder. It is progressive and incurable, with a variable prognosis. While motor symptoms are the most common presenting features, non-motor symptoms (particularly cognitive impairment, depression and anxiety) become increasingly prominent as the disease progresses and significantly reduce quality of life.

Pathophysiology

Although pathogenic variants in several genes have been identified in a few cases, in most patients the cause remains unknown. The discovery that methyl-phenyl-tetrahydropyridine (MPTP) caused severe parkinsonism in young drug users suggested that PD might be due to an environmental toxin, but none has been convincingly identified. The pathological hallmarks of PD are depletion of the pigmented dopaminergic neurons in the substantia nigra and the presence of α-synuclein and other protein inclusions in nigral cells (Lewy bodies; Fig. 27.45). It is thought that environmental or genetic factors alter the α-synuclein protein, rendering it toxic and leading to Lewy body formation within the nigral cells. Lewy bodies are also found in the basal ganglia, brainstem and cortex, and increase with disease progression. PD is recognised as a synucleinopathy alongside multiple system atrophy and dementia with Lewy bodies. The loss of dopaminergic neurotransmission is responsible for many of the clinical features.

Clinical features

Non-motor symptoms, including reduction in sense of smell (hyposmia), anxiety/depression, constipation and REM sleep behavioural disturbance (RBD), may precede the development of typical motor features by many years, but patients rarely present at this stage. The motor symptoms are almost always initially asymmetrical. The hallmark is bradykinesia, leading to classic symptoms such as increasingly small handwriting ('micrographia'), difficulty tying shoelaces or buttoning clothes, and difficulty rolling over in bed. Tremor is an early feature but may not be present in at least 20% of people with PD. It is typically a unilateral rest tremor affecting limbs, jaw and chin but not the head. In some patients tremor remains the dominant symptom for many years. Rigidity causes stiffness and a flexed posture. Although postural righting reflexes are impaired early on in the disease, falls tend not to occur until later. As the disease advances, speech becomes softer and indistinct. There are a number of abnormalities on neurological examination (Box 27.65).

Although features are initially unilateral, gradual bilateral involvement evolves with time. Cognition is spared in early disease; if impaired, it should trigger consideration of alternative diagnoses, such as dementia with Lewy bodies.

Non-motor symptoms

While non-motor symptoms may precede the onset of more typical symptoms by many years, for most patients these features become increasingly common and disabling as PD progresses. Cognitive impairment, including dementia, is the symptom most likely to impair quality of life for patients and their carers. Estimates of dementia frequency range from 30% to 80%, depending on definitions and length of follow-up. Other distressing non-motor symptoms include neuropsychiatric features (anxiety, depression, apathy, hallucinosis/psychosis), sleep disturbance and hypersomnolence, fatigue, pain, sphincter disturbance and constipation, sexual problems (erectile failure, loss of libido or hypersexuality), drooling and weight loss.

Investigations

The diagnosis is clinical. Structural imaging (CT or MRI) is usually normal for age and thus rarely helpful, although it may support a suspected vascular cause of parkinsonism. Functional dopaminergic imaging (SPECT or PET) is abnormal, even in the early stages (Fig. 27.46), but does not differentiate between the different forms of degenerative parkinsonism (see Box 27.64) and so is not specific for PD. In younger patients, specific investigations may be appropriate (e.g. exclusion of Huntington or Wilson diseases). Some patients with

i 27.65 Physical signs in Parkinson disease

General

- Expressionless face (hypomimia)
- Soft, rapid, indistinct speech (dysphonia)
- Flexed (stooped) posture
- Impaired postural reflexes

Gait

- Slow to start walking (failure of gait ignition)
- Rapid, short stride length, tendency to shorten (festination)
- Reduction of arm swing
- Impaired balance on turning

Tremor

Resting (3–4 Hz, moderate amplitude): most common

- Asymmetric, usually first in arm/hand ('pill rolling')
- May affect legs, jaw and chin
- Intermittent, present at rest, often briefly abolished by movement of the arm, exacerbated by walking (reduced arm swing on the more affected side when walking and the tremor often appears in the affected hand)

Postural (6–8 Hz, moderate amplitude)

- Present on stretching out arms

Re-emergent tremor (3–4 Hz, moderate amplitude)

- Initially no tremor on stretching arms out, rest tremor re-emerges after a few seconds

Rigidity

- Cogwheel type, mostly upper limbs (due to tremor superimposed on rigidity)
- Lead pipe type

Akinesia (fundamental feature)

- Slowness of movement
- Fatiguing and decrease in size of repetitive movements

Normal findings (if abnormal, consider other causes)

- Power, deep tendon reflexes, plantar responses
- Eye movements
- Sensory and cerebellar examination

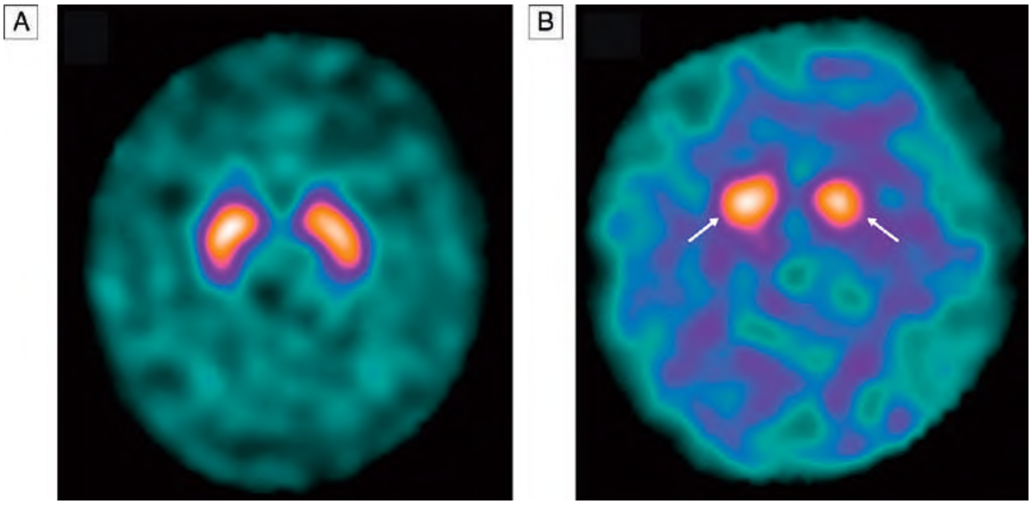

Fig. 27.46 **Imaging in Parkinson disease.** A ^{123}I-ioflupane (DaT) SPECT scan demonstrating normal uptake within the caudate and putamen bilaterally. B Loss of uptake within the putamen bilaterally with preservation of uptake within the caudate nuclei (arrows) and increased background activity in a patient with Parkinson disease.

family histories may wish to consider genetic testing, although the role of genetic counselling is uncertain at present.

Management

Drug therapy

Drug treatment for PD remains symptomatic rather than curative, and there is no evidence that any of the currently available drugs are neuroprotective. Levodopa (LD) remains the most effective treatment available, but other agents include dopamine agonists, anticholinergics, inhibitors of monoamine oxidase (MAOI)-B and catechol-O-methyl-transferase (COMT), and amantadine. Debate continues about when and what treatment should be started. In general, most specialists recommend initiating treatment when symptoms are impacting on everyday life, although some favour treatment as soon as the diagnosis is made. Whether it is best to start with LD, a dopamine agonist or MAOI-B remains unclear, but most accept that the most effective, best-tolerated and cheapest drug is LD. Many motor symptoms, such as tremor, freezing, falling, head-drop and abnormal flexion, are quite resistant to treatment. Some non-motor symptoms, such as anxiety or depression, may respond to drug or non-drug treatments. In the UK, rivastigmine is licensed for use in PD-associated dementia, although its effect is modest. Many other non-motor symptoms are resistant to treatment. Drugs for PD should not be stopped abruptly, as this can precipitate malignant hyperthermia.

Levodopa Levodopa is the precursor to dopamine. When administered orally, more than 90% is decarboxylated to dopamine peripherally in the gastrointestinal tract and blood vessels, and only a small proportion reaches the brain. This peripheral conversion is responsible for the high frequency of adverse effects. To avoid this, LD is combined with a dopa decarboxylase inhibitor (DDI); the inhibitor does not cross the blood–brain barrier, thus avoiding unwanted decarboxylation-blocking in the brain. Two DDIs, carbidopa and benserazide, are available as combination preparations with LD (Sinemet and Madopar, respectively).

LD is most effective for relieving akinesia and rigidity; tremor response is often less satisfactory and it has no effect on many motor (posture, freezing) and non-motor symptoms. Failure of akinesia/rigidity to respond to LD (1000 mg/day) should prompt reconsideration of the diagnosis. Although controlled-release versions of LD exist, these are usually best reserved for use overnight, as their variable bioavailability makes them difficult to use throughout the day. Madopar is also available as a dispersible tablet for more rapid-onset effect.

Adverse effects include postural hypotension, nausea and vomiting, which may be offset by domperidone, though this is only prescribed for brief periods, if essential, given the risk of prolonged QTc interval and arrhythmia. LD may exacerbate or trigger hallucinations, and abnormal LD-seeking behaviour (dopamine dysregulation syndrome), in which the patient takes excessive doses of LD, may occur uncommonly.

As PD progresses, the response to LD becomes less predictable in many patients, leading to motor fluctuations. This end-of-dose deterioration is due to progressive loss of dopamine storage capacity by dwindling numbers of striatonigral neurons. LD-induced involuntary movements (dyskinesia) may occur as a peak-dose phenomenon or as a biphasic phenomenon (occurring during both the build-up and wearing-off phases). More complex fluctuations present as sudden, unpredictable changes in response, in which periods of parkinsonism ('off' phases) alternate with improved mobility but with dyskinesias ('on' phases). Motor complication management is difficult; wearing-off effects may respond to increased dose or frequency of LD or the addition of a COMT inhibitor (see below). More complex fluctuations may be improved by the addition of dopamine agonists (including continuous infusion of apomorphine), use of intraintestinal LD via a percutaneous endoscopic jejunostomy, or deep brain stimulator implantation. Foslevodopa/foscarbidopa, a device-assisted 24-hour continuous subcutaneous infusion, is a recent development for treating advanced Parkinson disease.

Dopamine receptor agonists Originally introduced in the hope of delaying the initiation of LD and thus delaying motor complications, several dopamine agonists are available and may be delivered orally, transdermally, sublingually, intranasally or subcutaneously (Box 27.66). The side-effect of impulse control disorder (ICD) became apparent with widespread use of dopamine agonists resulting in, for example, gambling, hypersexuality, excessive carbohydrate consumption, obsessions and compulsions. All patients must be counselled about this risk and emergence of ICD monitored at review visits. If ICD occurs, the dopamine agonist should be withdrawn. Patients with pre-existing history of addictions or obsessive compulsive traits should probably avoid dopamine agonists.

27.66 Dopamine agonists*

Ergot-derived

- Bromocriptine
- Lisuride
- Pergolide
- Cabergoline

Non-ergot-derived

- Ropinirole
- Pramipexole
- Rotigotine (transdermal patch)
- Apomorphine (subcutaneous, nasal, sublingual)

*Oral unless otherwise stated.

The ergot-derived agonists are no longer recommended because of rare but serious fibrotic side-effects. With the exception of apomorphine, all the agonists are considerably less effective than LD in relieving parkinsonism, have more adverse effects (nausea, vomiting, disorientation and hallucinations, impulse control disorders) and are more expensive. Their role in the management of PD (monotherapy or adjunctive) remains uncertain, and evidence suggests that their usefulness as initial monotherapy is short-lasting.

MAOI-B inhibitors Monoamine oxidase type B facilitates breakdown of excess dopamine in the synapse. Two inhibitors are used in PD: selegiline and rasagiline. The effects of both are modest, although usually well tolerated. Neither is neuroprotective, despite initial hopes.

COMT inhibitors Catechol-O-methyl-transferase (along with dopa decarboxylase) is involved in peripheral breakdown of LD. Three inhibitors are available: entacapone, opicapone and tolcapone (which also inhibits central COMT). Entacapone has a modest effect and is most useful for early wearing-off. It is available either as a single tablet taken with each LD/DDI dose, or as a combination tablet with LD and DDI. The more potent tolcapone is less used because of rare but serious hepatotoxicity. Opicapone, the newest of the three, is available as a once-daily drug.

Amantadine This has a mild, usually short-lived effect on bradykinesia and is rarely used unless patients are unable to tolerate other drugs. It is more commonly employed as a treatment for LD-induced dyskinesias, although again benefit is modest and short-lived. Adverse effects include livedo reticularis, peripheral oedema, delirium and other anticholinergic effects.

Anticholinergic drugs These were the main treatment for PD prior to the introduction of LD. Their role now is limited by lack of efficacy (apart from an effect on tremor sometimes) and adverse effects, including dry mouth, blurred vision, constipation, urinary retention, delirium and hallucinosis, as well as long-term concerns regarding cognitive impairment. Several anticholinergics are available, including trihexyphenidyl (benzhexol) and orphenadrine.

Surgery

Destructive neurosurgery was commonly used before the introduction of LD. In the last 20 years, stereotactic surgery has emerged and most commonly involves deep brain stimulation (DBS), rather than the destructive approach of previous eras. Various targets have been identified, including the thalamus (only effective for tremor), globus pallidus and subthalamic nucleus. DBS is usually reserved for individuals with medically refractory tremor or motor fluctuations, and careful patient selection is vital to success. Intracranial delivery of fetal grafts or specific growth factors remains experimental. MRI-guided ultrasound-induced thalamotomy is a relatively new but increasingly used treatment for tremor; long-term outcomes are not well established.

Physiotherapy, occupational therapy and speech therapy

Patients at all stages of PD benefit from physiotherapy, which helps reduce rigidity and corrects abnormal posture. Occupational therapists can provide equipment to help overcome functional limitations, such as rails for stairs and the toilet, and bathing equipment. Speech therapy can help where dysarthria and dysphonia interfere with communication, and advice may also be provided to those with dysphagia. As with many complex neurological disorders, patients with PD should ideally be managed by a multidisciplinary team, including PD specialist nurses.

Other Parkinsonian syndromes

Cerebrovascular disease and drug-induced parkinsonism are the most common alternative causes of parkinsonism (see Box 27.64). There are several degenerative conditions that cause parkinsonism, including multiple system atrophy, progressive supranuclear palsy and corticobasal degeneration. They typically have a more rapid progression than PD and tend to be resistant to treatment with LD. They are defined pathologically and identification during life is difficult. There are other conditions that may rarely manifest as parkinsonism, including Huntington and Wilson diseases.

Multiple system atrophy

Multiple system atrophy (MSA) is characterised by parkinsonism, autonomic failure and cerebellar symptoms, with either parkinsonism (MSA-P) or cerebellar features (MSA-C) predominating. It is much less common than PD, with a prevalence of about 4/100 000. Although early distinction between PD and MSA-P may be difficult, early falls, postural instability and lack of response to LD are clues. The pathological hallmark is α-synuclein-containing glial cytoplasmic inclusions found in the basal ganglia, cerebellum and motor cortex. Management is symptomatic and the prognosis is less good than for PD, with mean survival from symptom onset of fewer than 10 years and early disability. Cognition is usually unaffected.

Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) presents with symmetrical parkinsonism, cognitive impairment, early falls and bulbar symptoms. The characteristic eye movement disorder, with slowed vertical saccades leading to impairment of up- and down-gaze, may take years to emerge. PSP has different pathological features, being associated with abnormal accumulation of tau (τ) proteins and degeneration of the substantia nigra, subthalamic nucleus and mid-brain. It is therefore considered a tauopathy rather than synucleinopathy. The prevalence is about 5/100 000, with average survival similar to that in MSA. There is no treatment, and the parkinsonism usually does not respond to LD.

Corticobasal degeneration

Corticobasal degeneration (CBD) is less common than MSA or PSP, and the clinical manifestations are variable, including parkinsonism, dystonia, myoclonus and 'alien limb' phenomenon, whereby a limb (usually upper) moves about or interferes with the other limb without apparent conscious control. Cortical symptoms, including dementia and especially apraxia, are common and may be the only features in some cases. A number of other diseases may present with a corticobasal syndrome, including other dementias. CBD is a tauopathy with widespread deposition throughout the brain and has similar survival rates to MSA and PSP.

Wilson disease

This is an autosomal recessive disorder resulting from pathogenic variants in the *ATP7B* gene, causing a defect of copper metabolism (p. 926). It is a treatable cause of various movement disorders, including tremor, dystonia, parkinsonism and ataxia; psychiatric symptoms may also occur. Wilson disease should always be excluded in patients under the age of 50 presenting with any movement disorder.

Huntington disease

Huntington disease (HD) is an autosomal dominant disorder, presenting in adults usually but occasionally in children. It is due to expansion of a trinucleotide CAG repeat in the *Huntingtin* gene on chromosome 4 (see Box 3.2). The disease frequently demonstrates the phenomenon of anticipation, in which there is a younger age at onset as the disease is passed through generations, due to progressive expansion of the repeat. The prevalence is about 4–8/100 000.

Clinical features

HD typically presents with a progressive behavioural disturbance, abnormal movements (usually chorea) and cognitive impairment leading to dementia. Onset under 18 years is rare but patients may then present with parkinsonism rather than chorea (the 'Westphal variant'). There is always a family history, although this may not always be apparent and can sometimes be concealed.

Investigations and management

The diagnosis is confirmed by genetic testing; pre-symptomatic testing for other family members is available but must be preceded by appropriate counselling. Brain imaging may show caudate atrophy but is not a reliable test. There are a number of HD mimics.

Management is symptomatic, though antisense oligonucleotide therapy to reduce the Huntingtin gene (*HTT*) product is currently being trialled. The chorea may respond to neuroleptics such as risperidone or sulpiride, or tetrabenazine. Depression and anxiety are common and may be helped by medication.

Ataxias

The ataxias are a heterogeneous group of inherited and acquired disorders, presenting either with pure ataxia or in association with other neurological and non-neurological features. The differential is wide (Boxes 27.67 and 27.68), and diagnosis is guided by age of onset,

i 27.67 Causes of acquired ataxia

Structural

- Brain tumour
- Brain abscess

Toxic

- Drugs: lithium, several antiepileptics (including phenytoin, carbamazepine, lamotrigine and valproate), amiodarone, toluene, 5-fluorouracil, cytosine arabinoside
- Alcohol
- Heavy metals/chemicals: mercury, lead, thallium

Infection/post-infectious

- HIV
- Varicella zoster
- Whipple disease
- Miller Fisher syndrome (p. 1193)

Degenerative

- Multiple system atrophy
- Sporadic Creutzfeldt–Jakob disease
- Idiopathic (or sporadic) late-onset cerebellar ataxia

Inflammatory/immune-mediated

- Multiple sclerosis
- Gluten ataxia (coeliac disease)
- Paraneoplastic ataxia
- Hashimoto encephalopathy

Metabolic

- Vitamin B_1 or E deficiency
- Hypothyroidism
- Hypoparathyroidism

Vascular

- Stroke (ischaemic or haemorrhagic)
- Vascular malformations
- Superficial siderosis

27.68 Inherited ataxias

Inheritance pattern	Age of onset	Clinical features
Autosomal dominant		
Episodic ataxias	Childhood and early adulthood	Brief episodes of ataxia, sometimes induced by stress or startle. May develop progressive ataxia
Spinocerebellar ataxias (SCAs)	Childhood to middle age	Over 35 subtypes identified. Progressive ataxia, sometimes associated with other features, e.g. retinitis pigmentosa, pyramidal tract abnormalities, peripheral neuropathy and cognitive deficits
Dentato-rubro-pallidoluysian atrophy (DRPLA)	Childhood to middle age	Children present with myoclonic epilepsy and progressive ataxia. Adults have progressive ataxia with psychiatric features, dementia and choreoathetosis
Autosomal recessive		
Friedreich ataxia	Childhood/adolescence (late onset possible)	Ataxia, nystagmus, dysarthria, spasticity, areflexia, proprioceptive impairment, diabetes mellitus, optic atrophy, cardiac abnormalities. Usually chair-bound
Ataxia telangiectasia	Childhood	Progressive ataxia, athetosis, telangiectasia on conjunctivae, impaired DNA repair, immune deficiency, tendency to malignancies
Abetalipoproteinaemia	Childhood	Steatorrhoea, sensorimotor neuropathy, retinitis pigmentosa, malabsorption of vitamins A, D, E and K
Hereditary ataxia with vitamin E deficiency	< 20 years	Similar to Friedreich ataxia, visual loss or retinitis pigmentosa, chorea
Others	Usually young onset	Numerous, with genes identified only in some
X-linked		
Fragile X tremor ataxia syndrome	> 50 years	Tremor, ataxia, parkinsonism, autonomic failure, cognitive impairment and dementia
Adrenoleukodystrophy	Childhood to adult	Impaired adrenal and cognitive function, sometimes spastic paraparesis
Mitochondrial disease	Various	Ataxia features in several mitochondrial diseases, including Kearns–Sayre syndrome, MELAS, MERRF, Leigh syndrome

(MELAS = mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MERRF = myoclonic epilepsy with ragged red fibres)

27.69 Drug-induced tremor (usually postural)*

- β-agonists (e.g. salbutamol)
- Theophylline
- Sodium valproate
- Thyroxine
- Lithium
- Tricyclic antidepressants
- Recreational drugs (e.g. amphetamines)
- Alcohol
- Caffeine

*Drugs causing parkinsonism and associated tremor are listed in Box 27.64.

evolution and clinical features. A significant proportion of cases remain idiopathic despite investigation.

The hereditary ataxias are a group of inherited disorders in which degenerative changes occur to varying extents in the cerebellum, brainstem, pyramidal tracts, spinocerebellar tracts and optic and peripheral nerves, and influence the clinical manifestations. Onset ranges from infancy to adulthood, with recessive, sex-linked or dominant inheritance (see Box 27.68). While the genetic abnormality has been identified for some, allowing diagnostic testing, this is not currently the case for many of the hereditary ataxias.

Tremor disorders

Tremor is a feature of many disorders but the most important clinical syndromes are PD, essential tremor, drug-induced tremors (Box 27.69) and functional tremors (p. 1183).

Essential tremor

This has a prevalence of about 300/100 000 and may display a dominant pattern of inheritance, although no genes have thus far been identified. It may present at any age with a bilateral arm tremor (8–10 Hz), rarely at rest but typical with movement. The head and voice may be involved. The tremor improves in about 50% of patients with small amounts of alcohol. There are no specific tests and essential tremor should be distinguished from other tremor syndromes, including dystonic tremor. Beta-blockers and primidone are sometimes helpful, and DBS of the thalamus is an effective treatment for severe cases.

Dystonia

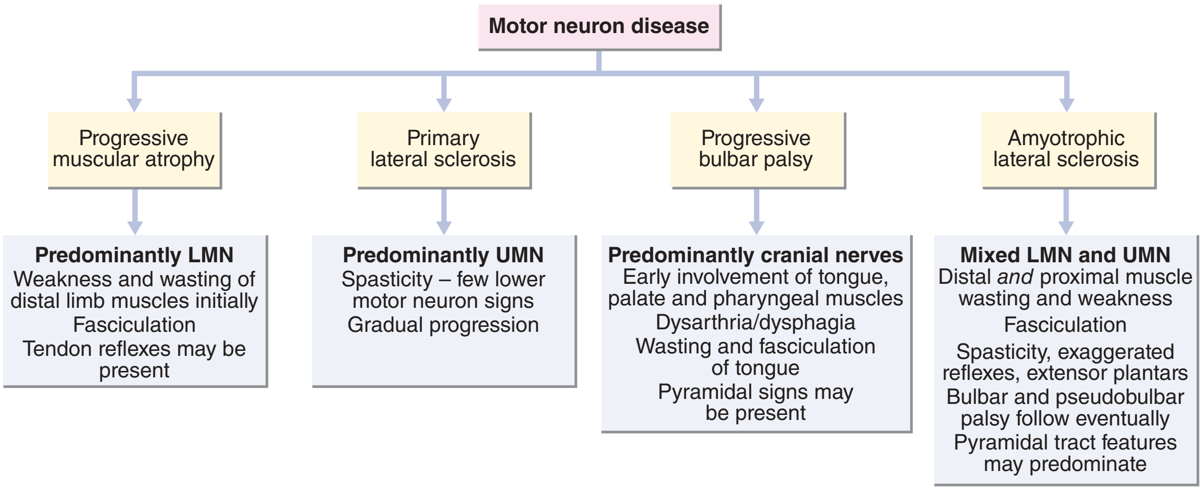
Dystonia is characterised by a focal increase in tone affecting muscles in the limbs or trunk. It may be a feature of a number of neurological conditions (PD, Wilson disease), or occur secondary to brain damage (trauma, stroke) or drugs (tardive syndromes). Dystonia also occurs as a primary disorder. With childhood onset the cause is usually genetic and dystonia is generalised, but adult onset is usually focal; examples include a twisted neck (torticollis), repetitive blinking (blepharospasm) or tremor. Task-specific symptoms (e.g. writer's cramp, musician's dystonia) are often dystonic. Treatment is difficult but botulinum toxin injections or DBS may be useful.

Hemifacial spasm

This usually presents after middle age with intermittent twitching around one eye, spreading ipsilaterally to other facial muscles. The spasms are exacerbated by talking, eating and stress. Hemifacial spasm is usually idiopathic, similar to trigeminal neuralgia; it has been suggested that it may be due to an aberrant arterial loop irritating the 7th nerve just outside the pons. It may, however, be symptomatic and secondary to structural lesions. Drug treatment is not effective but injections of botulinum toxin into affected muscles help, although these usually have to be repeated every 3 months or so. In refractory cases, microvascular decompression may be considered.

Motor neuron disease

Motor neuron disease (MND) is a neurodegenerative condition caused by loss of upper and lower motor neurons in the spinal cord, cranial nerve nuclei



Motor neuron disease
Progressive muscular atrophy
Primary lateral sclerosis
Progressive bulbar palsy
Amyotrophic lateral sclerosis
Predominantly LMN
Weakness and wasting of distal limb muscles initially
Fasciculation
Tendon reflexes may be present
Predominantly UMN
Spasticity – few lower motor neuron signs
Gradual progression
Predominantly cranial nerves
Early involvement of tongue, palate and pharyngeal muscles
Dysarthria/dysphagia
Wasting and fasciculation of tongue
Pyramidal signs may be present
Mixed LMN and UMN
Distal *and* proximal muscle wasting and weakness
Fasciculation
Spasticity, exaggerated reflexes, extensor plantars
Bulbar and pseudobulbar palsy follow eventually
Pyramidal tract features may predominate

Fig. 27.47 **Patterns of involvement in motor neuron disease.** (LMN = lower motor neuron; UMN = upper motor neuron)

i 27.70 Clinical features of motor neuron disease

Onset

- Usually after the age of 50 years
- Very uncommon before the age of 30 years
- Affects males more commonly than females

Symptoms

- Limb muscle weakness, cramps, occasionally fasciculation
- Disturbance of speech/swallowing (dysarthria/dysphagia)
- Cognitive and behavioural features common (similar to frontotemporal dementia)

Signs

- Wasting and fasciculation of muscles
- Weakness of muscles of limbs, tongue, face and palate
- Pyramidal tract involvement, causing spasticity, exaggerated tendon reflexes, extensor plantar responses
- External ocular muscles and sphincters usually remain intact
- No objective sensory deficit
- Evidence of cognitive impairment with frontotemporal dominance

Course

- Symptoms often begin focally in one part and spread gradually but relentlessly to become widespread

and motor cortex. Annual incidence is about 2/100 000, with a prevalence of about 7/100 000. Most cases are sporadic but 10% of cases are familial and pathogenic variations are found in many of these monogenic cases and may influence clinical phenotype and course, in particular overlap with frontotemporal dementia. The most common form of MND (Fig. 27.47) is amyotrophic lateral sclerosis (ALS), and many use the terms MND and ALS interchangeably. ALS is characterised by a combination of upper and lower motor neuron signs; there are rarer, pure lower (progressive muscular atrophy) or upper (progressive lateral sclerosis) motor neuron variants of MND. The average age of onset is 65, with 10% presenting before 45 years.

Clinical features

Diagnosis can be difficult and is often delayed. MND typically presents focally, either with limb onset (e.g. foot drop or loss of manual dexterity) or with bulbar symptoms (dysarthria, swallowing difficulty); respiratory onset is rare but type II respiratory failure is a common cause of death. Sensory, autonomic and visual symptoms do not occur, although cramp is common (Box 27.70). Examination reveals a combination of lower and upper motor neuron signs (e.g. brisk reflexes in wasted, fasciculating muscles) without sensory involvement (see Fig. 27.47). Cognitive impairment is under-recognised in MND: up to 50% will have a mainly executive impairment on formal testing, and around 10% develop a frontotemporal dementia (FTD). About 10% of patients presenting with FTD will develop ALS within a few years of dementia onset. Even with treatment, MND is relentlessly progressive, but median survival is improved with specialist follow-up offering non-invasive ventilation, feeding measures and access to pharmacological treatment.

Investigations

Clinical features are often typical but alternative diagnoses should be excluded. Exclusion of treatable causes, such as immune-mediated multifocal motor neuropathy with conduction block (p. 1236) and cervical myeloradiculopathy, is essential. Blood tests are usually normal, other than a mildly raised creatine kinase. Sensory and motor nerve conduction studies are normal, but there may be reduction in amplitude of motor action potentials due to axonal loss. EMG will usually confirm the typical features of widespread denervation and re-innervation. Spinal fluid analysis is not usually necessary. Genetic testing is increasing in importance, with pathogenic variations found in *SOD1*, *FUS*, *TARDBP* and *C9orf72* that may help predict risk of disease in those with a family history of MND.

Management

Patients should be managed within a multidisciplinary service, including physiotherapists, speech and occupational therapists, dietitians, ventilatory and feeding support, and palliative care teams, with neurological and respiratory input. Riluzole, a glutamate release antagonist, is licensed for ALS but has only a modest effect, prolonging median survival by about 2–3 months.

Non-invasive ventilation significantly prolongs survival and improves or maintains quality of life in people with ALS. Survival and some measures of quality of life are significantly improved in the subgroup of people with better baseline bulbar function but not in those with severe bulbar impairment. Feeding by percutaneous gastrostomy may improve quality of life and prolong survival, even when done at a late stage. Rapid access to palliative care teams is essential for patients as they enter the terminal stages of MND.

Spinal muscular atrophy

This is a group of genetically determined recessive disorders affecting spinal and cranial lower motor neurons, characterised by proximal and distal wasting, fasciculation and weakness of muscles. Most SMA cases are caused by a defective *SMN1* gene. Involvement is usually symmetrical but occasional localised forms occur. With the exception of the infantile form, progression is slow and the prognosis better than for MND. Nucleic acid–based therapies for the treatment of SMA have shown significant promise. Intrathecally delivered antisense oligonucleotide therapies can partially correct this *SMN1* genetic defect and show clinical efficacy in severe forms of the disease.

Infections of the nervous system

The clinical features of nervous system infections depend on the location of the infection (the meninges or the parenchyma of the brain and spinal cord), the causative organism (virus, bacterium, fungus or parasite), and whether the infection is acute or chronic. The major infections of the nervous system are listed in Box 27.71. The frequency of these varies geographically and in relation to socioeconomic level. While certain infections, e.g. tuberculosis and cysticercosis, may not be prevalent in the United Kingdom, they are common in other regions and therefore occur in returning travellers or immigrants. Protozoal infections are described in Chapter 14.

Meningitis

The characteristic clinical features of acute infection of the meninges are pyrexia, headache and meningism. Meningism consists of headache, photophobia and stiffness of the neck, sometimes accompanied by other signs of meningeal irritation, including Kernig sign (extension at the knee with the hip joint flexed causes spasm in the hamstring muscles) and Brudzinski sign (passive flexion of the neck causes flexion of the hips and knees). However, as discussed in Chapter 1, meningitis frequently presents without meningism, and although Kernig and Brudzinski signs are specific, their sensitivity can be as low as 5%. Therefore, meningitis should be considered in anyone who presents with fever and headache. Altered level of consciousness may occur and is more common in older people. Abnormalities in the CSF (see Box 27.6) are important in distinguishing the cause of meningitis. Causes of meningitis are listed in Box 27.72.

Viral meningitis

Viruses are the most common cause of meningitis, usually resulting in a benign and self-limiting illness requiring no specific therapy. It is much less serious than bacterial meningitis unless there is associated encephalitis. A number of viruses can cause meningitis (see Box 27.72), the most common being enteroviruses. Where specific immunisation is not employed, the mumps virus is a common cause.

Clinical features

Viral meningitis occurs mainly in children or young adults, with acute onset of headache and irritability and the rapid development of meningism. The headache is usually the most severe feature. There may be a high pyrexia but focal neurological signs are rare.

Investigations

The diagnosis is made by lumbar puncture, with the specific viral cause identified by a nucleic acid amplification test (NAAT). CSF usually contains an excess of lymphocytes. While glucose and protein levels are commonly normal, the latter may be raised. It is important to verify that the patient has not received antibiotics (for whatever cause) prior to the lumbar puncture, as CSF lymphocytosis can also be found in partially treated bacterial meningitis (see Box 27.6).

Management

There is no specific treatment and the condition is usually benign and self-limiting. The patient should be treated symptomatically in a quiet environment. Recovery usually occurs within days, although a lymphocytic pleocytosis may persist in the CSF. Meningitis may also occur as a complication of a systemic viral infection such as mumps, measles, infectious mononucleosis, varicella zoster and hepatitis. Whatever the virus, complete recovery without specific therapy is the rule.

Bacterial meningitis

Many bacteria can cause meningitis but geographical patterns vary, as does age-related sensitivity (Box 27.73). In the 'meningitis belt' of sub-Saharan Africa, drought and dust storms are often associated with meningococcal outbreaks (Harmattan meningitis). Bacterial meningitis is usually part of a

27.71 Infections of the nervous system

Bacterial infections

- Meningitis
- Suppurative encephalitis
- Brain abscess
- Paravertebral (epidural) abscess

Fungal infections

- *Candida* meningitis or brain abscess
- Cryptococcal meningitis

*These infections are discussed in Chapter 14.

27.72 Causes of meningitis

Infective

Bacteria

- *Streptococcus pneumoniae*
- *Neisseria meningitidis* (serogroups A, B, C, Y, W135)
- *Mycobacterium tuberculosis*
- *Haemophilus influenzae*
- *Listeria monocytogenes*
- Other streptococci including *Strep. suis*
- *Staphylococcus aureus* (skull fracture)

Viruses

- Enteroviruses (echo, Coxsackie, polio)
- Herpes simplex virus type 2 (Mollaret meningitis)
- Varicella zoster virus
- Herpes simplex type 1
- Epstein–Barr virus
- Cytomegalovirus
- Measles
- Mumps
- Other viruses
  - Lymphocytic choriomeningitis virus
  - West Nile virus
  - Human immunodeficiency virus

Fungi

- *Cryptococcus neoformans*
- *Candida*
- *Histoplasma*
- *Blastomyces*
- *Coccidioides*
- *Sporothrix*

Non-infective ('sterile')

Malignant disease

- Breast cancer
- Bronchogenic cancer
- Leukaemia
- Lymphoma

Inflammatory disease (may be recurrent)

- Sarcoidosis
- Systemic lupus erythematosus
- Behçet disease

27.73 Bacterial causes of meningitis at different ages

Age of onset	Common	Less common
Neonate	Gram-negative bacilli (*Escherichia coli*) Group B streptococci	*Listeria monocytogenes*
Pre-school child	*Haemophilus influenzae* *Neisseria meningitidis* (serogroups A, B, C, Y, W) *Streptococcus pneumoniae*	*Mycobacterium tuberculosis*
Older child and adult	*Strep. pneumoniae* *N. meningitidis* (serogroups A, B, C, Y, W) *M. tuberculosis* *H. influenzae*	*L. monocytogenes* Other streptococci *Staphylococcus aureus* (skull fracture)

bacteraemic illness, although direct spread from an adjacent focus of infection in the ear, skull fracture or sinus can be causative. Antibiotics have rendered this less common but mortality and morbidity remain significant. An important factor in determining prognosis is early diagnosis and the prompt initiation of appropriate therapy. Most bacterial causes of meningitis are normal commensals of the upper respiratory tract. New and potentially pathogenic strains are acquired by droplet spread but close contact is necessary. The organism invades through the nasopharynx, and disseminates through surrounding tissue and blood vessels leading to meningitis. Epidemics of meningococcal meningitis occur, particularly in cramped living conditions or where the climate is hot and dry.

Pathophysiology

Streptococcus pneumoniae (pneumococcus) and *Neisseria meningitidis* (meningococcus) are the commonest cause of bacterial meningitis globally, including in the United Kingdom. *Streptococcus suis* is a rare zoonotic cause of meningitis associated with porcine contact, which is an important cause of meningitis in some parts of Asia, including Vietnam and Thailand. Infection stimulates an immune response, causing the pia–arachnoid membrane to become congested and infiltrated with inflammatory cells. Pus then forms in layers, which may later organise to form adhesions. These may obstruct the free flow of CSF, leading to hydrocephalus, or they may damage the cranial nerves at the base of the brain. Some degree of hearing loss occurs in more than half of survivors. The CSF pressure rises rapidly, the protein content increases, and there is a cellular reaction that varies in type and severity according to the nature of the inflammation and the causative organism. An obliterative endarteritis of the leptomeningeal arteries passing through the meningeal exudate may produce secondary cerebral infarction. The pro-inflammatory immune mediators released are particularly prominent in *Streptococcus pneumoniae* infection and may account for the poor prognosis associated with pneumococcal meningitis, especially in older adults.

Clinical features

The most common presenting features are fever and headache, which may also be associated with drowsiness and meningism. More than 90% of patients have any two of: headache, pyrexia, meningism and altered consciousness. Rash may occur in meningococcal meningitis. In severe bacterial meningitis the patient may be comatose, later developing focal neurological signs. Seizures may occur in around a quarter of patients. When accompanied by sepsis, presenting signs may evolve rapidly, with abrupt onset of obtundation due to cerebral oedema. Complications of meningococcal sepsis are listed in Box 27.74. Chronic meningococcaemia is a rare condition in which the patient can be unwell for weeks or even months with recurrent fever, sweating, joint pains and transient rash. In pneumococcal and *Haemophilus* infections there may be an accompanying otitis media. Pneumococcal meningitis may be associated with pneumonia and occurs especially in older patients, those with alcohol dependence as well as those with hyposplenism. *Listeria monocytogenes* causes meningitis and rhombencephalitis (brainstem encephalitis) in the immunosuppressed host as well as in people at the extremes of age (neonates and older adults).

27.74 Complications of meningococcal sepsis

- Rash (morbilliform, petechial or purpuric)
- Shock
- Intravascular coagulation
- Renal failure
- Peripheral gangrene
- Arthritis (septic or reactive)
- Waterhouse-Friderichsen syndrome
- Myocarditis
- Cochlear damage
- Pericarditis (septic or reactive)

Investigations

Lumbar puncture is mandatory unless there are contraindications. If the patient is drowsy and has focal neurological signs or seizures, is immunosuppressed, has undergone recent neurosurgery or has suffered a head injury, it is wise to obtain a CT to exclude a mass lesion (such as a cerebral abscess) before lumbar puncture because of the risk of coning. This should not, however, delay treatment of presumed meningitis. If lumbar puncture is deferred or omitted, it is essential to take blood cultures before starting empirical treatment (Fig. 27.48). Lumbar puncture will help differentiate the causative organism but the characteristic findings in bacterial meningitis listed in Box 27.6 are far from universal. A bloody tap may complicate CSF findings. The safest approach is to treat for bacterial meningitis if the white cell count is above normal and disregard the red cell count. Gram film and culture may allow identification of the organism. Blood cultures may be positive but if not, PCR techniques can be used on both blood and CSF to identify bacterial DNA for several days after antibiotic treatment has started.

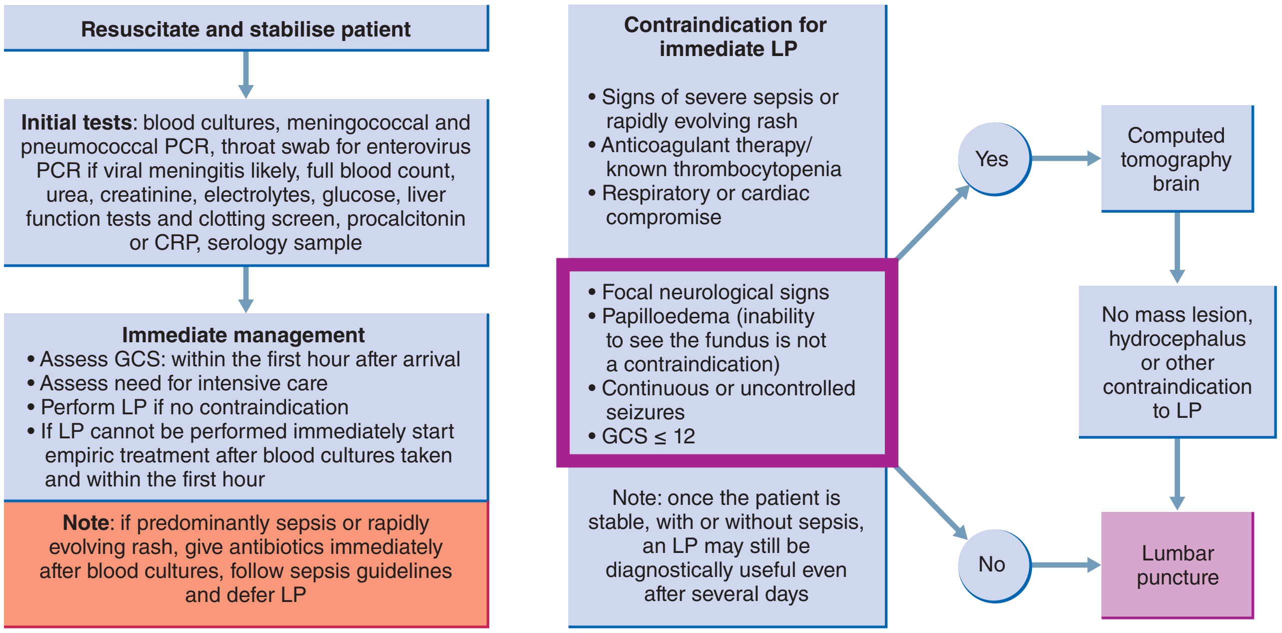
Management

There is an untreated mortality rate of around 80%, so action must be swift. Antibiotics should ideally be given after CSF and blood cultures have been obtained, but if there is an unacceptable delay obtaining these samples, antibiotic therapy should be started immediately. Recommended empirical therapies are outlined in Box 27.75, and the preferred antibiotic when the organism is known after CSF examination is stipulated in Box 27.76. Some regions of the world have a high prevalence of penicillin resistance and local guidelines or microbiologist advice should be sought. There is remarkably little evidence to guide duration of antibiotic treatment. As a guide, pneumococcal meningitis should be treated for 10–14 days, meningococcal meningitis slightly less (around 7 days) and *Listeria* meningitis for 21 days. Adjunctive glucocorticoid therapy given before or with the first dose of antibiotics is useful in reducing hearing loss and neurological sequelae in both children and adults in high-income countries, but evidence does not support the use of dexamethasone in lower-income countries or where there are high rates of untreated HIV.

In meningococcal disease, mortality is doubled if the patient presents with features of sepsis rather than meningitis. Individuals likely to require intensive care facilities and expertise include those with cardiac, respiratory or renal involvement, and those with CNS depression prejudicing the airway. Early endotracheal intubation and mechanical ventilation protect the airway and may prevent the development of the acute respiratory distress syndrome (ARDS). Adverse prognostic features include hypotensive shock, a rapidly developing rash, a haemorrhagic diathesis, multisystem failure and age over 60 years.

Prevention of meningococcal infection

Close contacts of patients with meningococcal infection (Box 27.77) should be given a single dose of ciprofloxacin. Rifampicin for two days is an alternative for those unable to take ciprofloxacin. If not treated with ceftriaxone or cefotaxime, the index case should be given similar treatment to clear infection from the nasopharynx before hospital discharge. Vaccines are available for most meningococcal subgroups.



Resuscitate and stabilise patient
Initial tests: blood cultures, meningococcal and pneumococcal PCR, throat swab for enterovirus PCR if viral meningitis likely, full blood count, urea, creatinine, electrolytes, glucose, liver function tests and clotting screen, procalcitonin or CRP, serology sample
Immediate management
• Assess GCS: within the first hour after arrival
• Assess need for intensive care
• Perform LP if no contraindication
• If LP cannot be performed immediately start empiric treatment after blood cultures taken and within the first hour
Note: if predominantly sepsis or rapidly evolving rash, give antibiotics immediately after blood cultures, follow sepsis guidelines and defer LP
Contraindication for immediate LP
• Signs of severe sepsis or rapidly evolving rash
• Anticoagulant therapy/ known thrombocytopenia
• Respiratory or cardiac compromise
• Focal neurological signs
• Papilloedema (inability to see the fundus is not a contraindication)
• Continuous or uncontrolled seizures
• GCS ≤ 12
Note: once the patient is stable, with or without sepsis, an LP may still be diagnostically useful even after several days
Yes
No
Computed tomography brain
No mass lesion, hydrocephalus or other contraindication to LP
Lumbar puncture

Fig. 27.48 **The investigation of meningitis based on the British Infection Association acute meningitis guideline.** (CRP = C-reactive protein; GCS = Glasgow Coma Scale; LP = lumbar puncture, PCR = polymerase chain reaction) *Adapted from the UK joint specialist societies guideline on the diagnosis and management of acute meningitis and meningococcal sepsis in immunocompetent adults. J Infect 2016;72:405–438.*

27.75 Treatment of bacterial meningitis of unknown cause (based on the British Infection Association Guideline 2016)*

1. Adults aged less than 60 years

- Cefotaxime 2 g IV 4 times daily *or*
- Ceftriaxone 2 g IV twice daily

2. Patients in whom penicillin-resistant pneumococcal infection is suspected, or in areas with a significant incidence of penicillin resistance in the community

As for (1) but add:

- Vancomycin 15–20 mg/kg IV twice daily *or*
- Rifampicin 600 mg IV or orally twice daily

3. Adults aged > 60 years and those in whom *Listeria monocytogenes* infection is suspected (brainstem signs, immunosuppression, diabetic, alcohol misuser)

As for (1) but add:

- Ampicillin 2 g IV 6 times daily *or*
- Amoxicillin 2 g IV 6 times daily

4. Adults aged > 60 years, or with risk factors in (3) above, in areas with a significant incidence of penicillin resistance in the community

As for (2) but add:

- Ampicillin 2 g IV 6 times daily *or*
- Amoxicillin 2 g IV 6 times daily

5. Patients with a clear history of anaphylaxis to β-lactams

- Chloramphenicol 25 mg/kg IV 4 times daily *plus*
- Vancomycin 15–20 mg/kg IV twice daily

If over the age of 60 years, add: co-trimoxazole 10–20 mg/kg (of the trimethoprim component) in four divided doses

6. Adjunctive treatment (see text)

- Dexamethasone 10 mg 4 times daily for 2–4 days

*N.B. Antibiotic recommendations depend on local epidemiology of organisms and antibiotic resistance. Local guidance should always be sought.

British Infection Association Guideline in Journal of Infection 2016;72:405–438.

27.76 Chemotherapy of bacterial meningitis when the cause is known (based on the British Infection Association Guideline 2016)[1]

Pathogen	Regimen of choice	Alternative agents
Neisseria meningitidis	Cefotaxime 2 g IV 4 times daily *or* ceftriaxone 2 g IV twice daily for 5–7 days	Benzylpenicillin 2.4 g IV 6 times daily *or* Chloramphenicol[2,3] 25 mg/kg 4 times daily for 5–7 days
Streptococcus pneumoniae (sensitive to β-lactams, MIC ≤ 0.06)	Cefotaxime 2 g IV 4 times daily *or* Ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol[2,3] 25 mg/kg 4 times daily for 10–14 days
Strep. pneumoniae (resistant to β-lactams)	As for sensitive strains but add: Vancomycin 15–20 mg/kg IV twice daily *or* Rifampicin 600 mg IV twice daily for 14 days	Chloramphenicol[3] 25 mg/kg 4 times daily for 14 days
Haemophilus influenzae	Cefotaxime 2 g IV 4 times daily *or* Ceftriaxone 2 g IV twice daily for 10 days	Moxifloxacin 400 mg daily for 10 days
Listeria monocytogenes	Amoxicillin 2 g IV 6 times daily for 21 days	Co-trimoxazole 10–20 mg/kg (of the trimethoprim component) daily in four divided doses for 21 days
Streptococcus suis	Cefotaxime 2 g IV 4 times daily *or* Ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol[2,3] 25 mg/kg 4 times daily for 10–14 days

[1] N.B. Antibiotic recommendations depend on local epidemiology of organisms and antibiotic resistance. Local guidance should always be sought.

[2] For patients with a history of anaphylaxis to β-lactam antibiotics. British Infection Association Guideline in *Journal of Infection* 2016;72:405–438.

[3] If the patient is recovering reduce the dose of chloramphenicol to 12.5 mg/kg to reduce the risk of dose-related anaemia. From Erratum to reference in note 2.

(IV = intravenous; MIC = minimum inhibitory concentration)

27.77 Chemoprophylaxis following meningococcal exposure

Close contacts warranting chemoprophylaxis

- Household contacts (including persons who ate or slept in the same dwelling as the patient during the 7 days prior to disease onset)
- Child-care and nursery-school contacts
- Persons having contact with patient's oral secretions during the 7 days prior to disease onset:
  - Kissing
  - Sharing of toothbrushes
  - Sharing of eating utensils
  - Mouth-to-mouth resuscitation
  - Unprotected contact during endotracheal intubation
- Aircraft contacts for persons seated next to the patient for > 8 hrs

Persons at low risk in whom chemoprophylaxis is not recommended

- Casual contact (e.g. at school or work) without direct exposure to patient's oral secretions
- Indirect contact only (contact with a high-risk contact and not a case)
- Health-care worker without direct exposure to patient's oral secretions

27.78 Clinical features and staging of tuberculous meningitis

Symptoms

- Headache
- Vomiting
- Low-grade fever
- Lassitude
- Depression
- Delirium
- Behaviour changes

Signs

- Meningism (may be absent)
- Oculomotor palsies
- Papilloedema
- Depression of conscious level
- Focal hemisphere signs

Staging of severity

- Stage I (early): non-specific symptoms and signs without alteration of consciousness
- Stage II (intermediate): altered consciousness without coma or delirium *plus* minor focal neurological signs
- Stage III (advanced): stupor or coma, severe neurological deficits, seizures or abnormal movements

Tuberculous meningitis

Tuberculous meningitis is now uncommon in high-income countries except in immunocompromised individuals, although it is still seen in those born in endemic areas and in low- and middle-resource countries. It is seen more frequently as a secondary infection in patients with HIV infection.

Pathophysiology

Tuberculous meningitis most commonly occurs shortly after a primary infection in childhood or as part of miliary tuberculosis. The usual local source of infection is a caseous focus in the meninges or brain substance adjacent to the CSF pathway. The brain is covered by a greenish, gelatinous exudate, especially around the base, and numerous scattered tubercles are found on the meninges.

Clinical features

The clinical features and staging criteria are listed in Box 27.78. Onset is much slower than in other bacterial meningitis – over 2–8 weeks. If untreated, tuberculous meningitis is fatal in a few weeks but complete recovery is usual if treatment is started at stage I (see Box 27.78). When treatment is initiated later, the rate of death or serious neurological deficit may be as high as 30%.

Investigations

Lumbar puncture should be performed if the diagnosis is suspected. The CSF is under increased pressure. It is usually clear but, when allowed to stand, a fine clot ('spider web') may form. The fluid contains up to 500×10^{6} cells/μL, predominantly lymphocytes, but can contain neutrophils. There is a rise in protein, often marked, and a similarly marked fall in glucose. The tubercle bacillus may be detected in a smear of the centrifuged deposit from the CSF but a negative result does not exclude the diagnosis. The CSF should be cultured but, as this result will not be known for up to 6 weeks, treatment must be started without waiting for confirmation. The WHO recommends use of additional nucleic acid amplification tests (NAATs), specifically Xpert MT/RIF Ultra. This should be used in addition to smear and culture studies, as NAATs are not sensitive enough to exclude tuberculous meningitis when negative. Brain imaging may show hydrocephalus, brisk particularly basal meningeal enhancement on enhanced CT or MRI, and/or uncommonly an intracranial tuberculoma.

Management

As soon as the diagnosis is made or strongly suspected, chemotherapy should be started using one of the regimens that include pyrazinamide, described on page 561. The use of glucocorticoids in addition to antituberculous therapy has been controversial. Recent evidence suggests that it improves mortality, especially if given early, but not focal neurological damage whether associated with HIV infection or not. Surgical ventricular drainage may be needed if obstructive hydrocephalus develops. Skilled nursing is essential during the acute phase of the illness, and adequate hydration and nutrition must be maintained.

Fungal meningitis

Fungal meningitis is uncommon and usually occurs in the immunosuppressed. The yeast *Cryptococcus neoformans* is the commonest and an important cause of meningitis in those immunosuppressed by HIV infection. It does occur in the immunocompetent although non-HIV forms of immunocompromise should be sought. The presentation may be atypical with subacute or chronic meningism, fever, headache and symptoms of raised intracranial pressure occur. The CSF opening pressure is often very raised, with 20–200 cells $\times10^{6}$/L mainly lymphocytes, elevated protein and low glucose levels (similar to findings in tuberculous meningitis) (see Box 27.6). In some regions the India ink test and cryptococcal PCR are used to detect cryptococci in the CSF. Cryptococcal antigen is present in the CSF and sometimes serum. Treatment is discussed on p. 330. Treatment of raised CSF pressure may be complex and frequent, sometimes daily, lumbar punctures are required.

Other meningitides

In some areas, meningitis may be caused by spirochaetes (leptospirosis, Lyme disease and syphilis), rickettsiae (typhus fever) or protozoa (primary amoebic meningoencephalitis, PAM).

Meningitis can also be due to non-infective pathologies. This is seen in recurrent aseptic meningitis resulting from systemic lupus erythematosus (SLE), Behçet disease or sarcoidosis, as well as a condition of previously unknown origin known as Mollaret syndrome, in which the recurrent meningitis is associated with epithelioid cells in the spinal fluid ('Mollaret' cells). Recent evidence suggests that this condition may be due to herpes simplex virus type 2 and is therefore infective after all. Meningitis can also be caused by direct invasion of the meninges by neoplastic cells ('malignant meningitis'; see Box 27.72).

Subdural empyema

This is a rare complication of frontal sinusitis, osteomyelitis of the skull vault or middle ear disease. A collection of pus in the subdural space spreads over the surface of the hemisphere, causing underlying cortical oedema or thrombophlebitis. Patients present with severe pain in the face or head and pyrexia, often with a history of preceding paranasal sinus or ear infection. The patient then becomes drowsy, with seizures and focal signs such as a progressive hemiparesis.

The diagnosis rests on a strong clinical suspicion in patients with a local focus of infection. Careful assessment with contrast-enhanced CT or MRI may show a subdural collection with underlying cerebral oedema. Management requires aspiration of pus via a burr hole and appropriate parenteral antibiotics. Any local source of infection must be treated to prevent re-infection.

Spinal epidural abscess

The characteristic clinical features are back pain, often in a nerve root distribution, and progressive transverse spinal cord syndrome with paraparesis, sensory impairment and sphincter dysfunction. There may be fever and raised inflammatory markers. Features of the primary focus of infection may be less obvious and thus can be overlooked. The resurgence of resistant staphylococcal infection and injection drug use has contributed to a recent marked rise in incidence.

Once the diagnosis is suspected, an MRI scan of the spine should be carried out (or myelography if MRI is not available). MRI is often negative in early disease, so if it is non-diagnostic and the clinical suspicion remains, it should be repeated after a week or so. Obtaining a bacteriological diagnosis is a high priority, and antibiotics are not usually started until this has been achieved (or at least attempted), e.g. by blood culture and tissue aspiration or biopsy. If there is spinal cord compression, surgical treatment is required (e.g. decompressive laminectomy with abscess drainage). However, in the absence of neurological impairment, treatment with antibiotics alone is often attempted, usually using intravenous antibiotics for at least 6 weeks, guided by clinical and biochemical response.

The spinal cord can be involved by other infections, including HTLV1, TB, schistosomiasis and echinococcus (Ch. 14).

Parenchymal viral infections

Infection of the substance of the nervous system will produce symptoms of focal dysfunction (deficits and/or seizures) with general signs of infection, depending on the acuteness of the infection and the type of organism.

Viral encephalitis

A range of viruses can cause encephalitis but only a minority of patients report recent systemic viral infection (Box 27.79). The relative importance of specific viruses depends on location and the specific population involved, e.g. immunosuppressed. In high-income countries, the most serious cause of viral encephalitis is herpes simplex, which probably reaches the brain via the olfactory nerves. The development of effective therapy for some forms of encephalitis has increased the importance of clinical diagnosis and virological examination of the CSF.

27.79 Causes of viral encephalitis (location dependent)

Virus	Locations	Comment
Sporadic encephalitides		
Herpes simplex virus type 1	Commonest cause; especially high-resource areas	Treatable, important to consider diagnosis early
Herpes simplex virus type 2	Around 10% of herpes simplex virus infections	Usually meningoencephalitis, may be recurrent
Varicella zoster virus	Increasing globally	Before, with or few days after vesicular rash. More common in immunosuppressed. Post infectious cerebellitis and cerebral vasculitis may occur
Enterovirus 70 and 71	Global, enterovirus 71, particularly Asia–Pacific region	Haemorrhagic conjunctivitis (enterovirus 70), hand foot and mouth disease and brainstem encephalitis (enterovirus 71)
Human immunodeficiency virus	Global	Around seroconversion
Measles and mumps	Global	Measles: post infectious or long-term subacute sclerosing panencephalitis. Mumps: before or after parotitis
Arbo- and zoonotic viruses (spread by ticks, mosquitoes and other vectors)		
West Nile virus	West and Central Asia, Middle East, Africa, Southern Europe and North America	*(Mosquito)* Profound flaccid weakness and rash; parkinsonism, myoclonus
Japanese encephalitis virus	Asia, Western Pacific	*(Pigs and wading birds)* Seizures very common, abnormal behaviour/psychosis, asymmetric flaccid paralysis, abnormal movement/parkinsonian
Dengue viruses	Asia, Pacific, Africa, Americas, Southern Europe	*(Mosquito)* Fever, arthralgia, rash, haemorrhagic manifestations, leucopenia
Chikungunya	Africa, Asia, Europe, Indian and Pacific Ocean islands, Americas	*(Mosquito)* Excruciating joint pain/arthritis, rash
Nipah and Hendra viruses	Asia–Pacific region, Hendra in Australia	*(Bats, human to human, intermediate transmission pigs, horses; Hendra – horse contact)* Nipah – segmental myoclonus, cerebellar signs, areflexia, multiple small (<5 mm) lesions on MRI
Rabies virus	Latin America, Caribbean, Asia, Africa, Central Asia and Middle East	*(Bats, dogs, cats)* Hyperactivity, painful pharyngeal and inspiratory muscle spasms, autonomic instability, hydrophobia
Other: St Louis virus, eastern, western, Venezuelan equine, La Crosse viruses/Colorado tick fever virus, Powassan virus	Americas mainly	*(Mosquitos/ticks)*
Zika virus	Africa, South-east Asia, Pacific islands, Americas, Caribbean	*(Mosquitos, human to human)* Pruritic rash, conjunctivitis, arthralgia hands and feet

(MRI = magnetic resonance imaging)

Pathophysiology

The infection provokes an inflammatory response that involves the cortex, white matter, basal ganglia and brainstem. The distribution of lesions varies with the type of virus. For example, in herpes simplex encephalitis, the temporal lobes are usually primarily affected, whereas cytomegalovirus can involve the areas adjacent to the ventricles (ventriculitis). Inclusion bodies may be present in the neurons and glial cells, and there is an infiltration of polymorphonuclear cells in the perivascular space. There is neuronal degeneration and diffuse glial proliferation, often associated with cerebral oedema.

Clinical features

Viral encephalitis presents with acute onset of headache, fever, focal neurological signs (aphasia and/or hemiplegia, visual field defects) and seizures. Disturbance of consciousness ranging from drowsiness to deep coma supervenes early and may advance dramatically. Meningism occurs in many patients. Additional clues to the causative virus are listed in Box 27.79. Rabies presents a distinct clinical picture and is described below.

Investigations

Imaging by CT scan may show low-density lesions in the temporal lobes but MRI is more sensitive in detecting early abnormalities. Lumbar puncture should be performed once imaging has excluded a mass lesion. The CSF usually contains excess lymphocytes but polymorphonuclear cells may predominate in the early stages. The CSF may be normal in up to 10% of cases. Some viruses, including the West Nile virus, may cause a sustained neutrophilic CSF. The protein content may be elevated but the glucose is normal. The EEG is usually abnormal in the early stages, especially in herpes simplex encephalitis, with characteristic periodic slow-wave activity in the temporal lobes. Virological investigations of the CSF, including PCR, may reveal the causative organism but treatment initiation should not await this.

Management

Optimum treatment for herpes simplex encephalitis (aciclovir 10 mg/kg IV 3 times daily adjusted for renal insufficiency for 2–3 weeks) has reduced mortality from 70% to around 10%. This should be given early to all patients suspected of having viral encephalitis. Patients should be kept well hydrated and renal function monitored frequently. The role of adjunctive dexamethasone is currently being evaluated in clinical trials.

Some survivors will have residual epilepsy or cognitive impairment. For details of post-infectious encephalomyelitis, see page 1208. Antiseizure treatment may be required and raised intracranial pressure may indicate the need for dexamethasone.

Brainstem encephalitis

This presents with ataxia, dysarthria, diplopia or other cranial nerve palsies. The CSF is lymphocytic, with a normal glucose. The causative agent is presumed to be viral. However, *Listeria monocytogenes* may cause a similar syndrome with meningitis (and often a polymorphonuclear CSF pleocytosis) and requires specific treatment with ampicillin (2 g 6 times daily; see Box 27.76).

Rabies

Rabies is caused by a rhabdovirus that infects the central nervous tissue and salivary glands of a wide range of mammals. It is usually conveyed by saliva through bites or licks on abrasions or on intact mucous membranes. Humans are most frequently infected from dogs and bats. In Europe, the maintenance host is the fox. The incubation period varies in humans from a minimum of 9 days to many months but is usually between 4 and 8 weeks. Severe bites, especially if on the head or neck, are associated with shorter incubation periods. Human rabies is a rare disease, even in endemic areas. However, because it is usually fatal, major efforts are directed at limiting its spread and preventing its importation into uninfected countries, such as the UK.

Clinical features

At the onset there may be fever, and paraesthesia at the site of the bite. A prodromal period of 1–10 days, during which the patient becomes increasingly anxious, leads to the characteristic ‘hydrophobia’. Although the patient is thirsty, attempts at drinking provoke violent contractions of the diaphragm and other inspiratory muscles. Delusions and hallucinations may develop, accompanied by spitting, biting and mania, with lucid intervals in which the patient is markedly anxious. Cranial nerve lesions develop and terminal hyperpyrexia is common. Death ensues, usually within a week of the onset of symptoms.

Investigations

During life, the diagnosis is usually made on clinical grounds but rapid immunofluorescent techniques can detect antigen in corneal impression smears or skin biopsies.

Management

Established disease

Only a few patients with established rabies have survived. All received some post-exposure prophylaxis (see below) and needed intensive care facilities to control cardiac and respiratory failure. Otherwise, only palliative treatment is possible once symptoms have appeared. The patient should be heavily sedated with diazepam, supplemented by chlorpromazine if needed. Nutrition and fluids should be given intravenously or through a gastrostomy.

Pre-exposure prophylaxis

Pre-exposure prophylaxis with rabies vaccine is required by those who handle potentially infected animals professionally, work with rabies virus in laboratories or live at special risk in rabies-endemic areas.

Post-exposure prophylaxis

The wounds should be thoroughly cleaned, preferably with a quaternary ammonium detergent or soap; damaged tissues should be excised and the wound left unsutured. Rabies can usually be prevented if treatment is started within a day or two of biting. Delayed treatment may still be of value. For maximum protection, hyperimmune serum and vaccine are required.

The safest anti-rabies antiserum is human rabies immunoglobulin. The dose is 20 IU/kg body weight; half is infiltrated around the bite and half is given intramuscularly at a different site from the vaccine. Hyperimmune animal serum may be used, but hypersensitivity reactions, including anaphylaxis, are common.

The safest vaccine, free of complications, is human diploid cell strain vaccine. Post-exposure treatment is complex and depends on a composite risk based on the risk by country and the category of exposure. Detailed advice may be available locally or on the UK website https://www.gov.uk/government/publications/rabies-post-exposure-prophylaxis-management-guidelines. For example, an unimmunised individual from a high-risk country exposed to direct contact with terrestrial mammal saliva should receive human rabies immunoglobulin and four doses of vaccine on days 0, 3, 7 and 21. If immunocompromised, they should receive five doses of vaccine on days 0, 3, 7, 14 and 30. In contrast, an individual in a low-risk country and no physical contact with terrestrial mammal saliva would not require post-exposure prophylaxis.

Human immunodeficiency virus (HIV) infection

Box 27.80 summarises the neurological manifestations of HIV infection. These are covered in detail in Chapter 14.

Poliomyelitis

Disease is caused by one of three polioviruses, which constitute a subgroup of the enteroviruses. Poliomyelitis has become much less common following the introduction of the Global Polio Eradication initiative.

27.80 Neurological manifestations of human immunodeficiency virus (HIV) infection and treatment side-effects

Neurocognitive manifestations

- HIV-associated neurocognitive disorder
- HIV-associated encephalopathy: subcortical dementia (psychomotor slowing and memory loss), depression, movement disorders

Stroke

- Ischaemic stroke (90%): HIV-associated vasculopathy (accelerated atherosclerosis, aneurysm, vasculitis, small vessel disease), cardioembolism (cardiomyopathy, ischaemic heart disease, endocarditis), opportunistic infection (causing meningitis or vasculitis), lymphoma involving blood vessels, coagulopathy
- Cerebral haemorrhage (< 10%): HIV-associated vasculopathy, thrombocytopenia, mycotic aneurysm

Other brain/cranial nerve involvement

- Bell palsy (often around seroconversion)
- Meningitis: aseptic around seroconversion, cryptococcal meningitis, tuberculous meningitis
- Mass lesions: toxoplasmosis, lymphoma, tuberculosis
- Encephalitis: HIV around seroconversion, cytomegalovirus, Epstein–Barr virus, varicella zoster virus (can also result in vasculitis)
- Progressive multifocal leucoencephalopathy
- Seizures
- Immune reconstitution syndrome*

Spinal cord, motor neuron and nerve root

- Motor neurone disease
- Vacuolar myelopathy (late stage)
- Other viral myelopathy (particularly herpes group of viruses)
- Radiculopathy (caused by cytomegalovirus, or tuberculous meningitis)

Peripheral nerve and plexus

- Acute inflammatory demyelinating polyneuropathy (AIDP)
- Chronic inflammatory demyelinating polyneuropathy (CIDP)
- Mononeuritis multiplex (vasculitic)
- Distal symmetric peripheral neuropathy
- Diffuse infiltrative lymphocytosis syndrome
- Brachial plexopathy
- Antiretroviral-associated neuropathy*

Muscle

- HIV-associated myopathy (inflammatory myopathy)
- Antiretroviral-associated myopathy*

*Treatment effect.

Incidence dropped from more than 350 000 cases in 1988 to 33 in 2018. However, incomplete immunisation still results in small numbers of cases. Transmission usually occurs through faecal–hand–oral contamination with primary replication in the lymphatic tissue of the gastrointestinal and oropharyngeal tracts.

The virus causes a lymphocytic meningitis and infects the grey matter of the spinal cord, brainstem and cortex. There is a particular propensity to damage anterior horn cells, especially in the lumbar segments.

Many patients recover fully after the initial phase of a few days of mild fever and headache. In other individuals, after a week of well-being, there is a recurrence of pyrexia, headache and meningism. Weakness may start later in one muscle group and can progress to widespread paresis. Respiratory failure may supervene if intercostal muscles are paralysed or the medullary motor nuclei are involved. Poliomyelitis virus may be cultured from CSF and stool. Second attacks are very rare but occasionally patients show late deterioration in muscle bulk and power many years after the initial infection (this is termed the 'post-polio syndrome').

Prevention of poliomyelitis is by immunisation with live Sabin vaccine, a collection of live attenuated polio viruses (oral poliovirus vaccine, OPV) in low- and middle-income regions. The advantages of OPV include cost, ease of administration and transmission of the vaccine virus to unimmunised contacts. In high-income countries where polio is now very rare, the live vaccine has been replaced by the Salk vaccine (IPV), a collection of inactivated polio viruses. Advantages include avoidance of vaccine-associated paralytic poliomyelitis and effective combination with other routine childhood vaccines.

Herpes zoster (shingles)

Herpes zoster is the result of reactivation of the varicella zoster virus that has lain dormant in a nerve root ganglion following chickenpox earlier in life. Reactivation may be spontaneous (as usually occurs in middle-aged or older adults) or due to immunosuppression (as in patients with diabetes, malignant disease or HIV).

Subacute sclerosing panencephalitis

This is a rare, chronic, progressive and eventually fatal complication of measles, presumably a result of an inability of the nervous system to eradicate the virus. It occurs in children and adolescents, usually many years after the primary virus infection. There is generalised neurological deterioration and onset is insidious, with intellectual deterioration, apathy and clumsiness, followed by myoclonic jerks, rigidity and dementia.

The CSF may show a mild lymphocytic pleocytosis and the EEG demonstrates characteristic periodic bursts of triphasic waves. Although there is persistent measles-specific IgG in serum and CSF, antiviral therapy is ineffective and death ensues within a few years.

Progressive multifocal leucoencephalopathy

This was originally described as a rare complication of lymphoma, leukaemia or carcinomatosis but is seen in untreated HIV/AIDS or secondary to immunosuppression, e.g. following organ transplantation or use of disease-modifying drugs for MS, in particular natalizumab. It is an infection of oligodendrocytes and other neuroglial cells by human polyomavirus JC, causing widespread demyelination of the white matter of the cerebral hemispheres. Clinical signs include dementia, hemiparesis and aphasia, which progress rapidly, usually leading to death within weeks or months. Areas of low density in the white matter are seen on CT but MRI is more sensitive, showing diffuse high signal in the cerebral white matter on T2-weighted images, sometimes with contrast enhancement. The only treatment available is restoration of the immune response (by treating HIV/AIDS or reversing immunosuppression) which can lead to the development of an immune reconstitution inflammatory syndrome (PML-IRIS).

Parenchymal bacterial infections

Cerebral abscess

Bacteria may enter the cerebral substance through penetrating injury, by direct spread from paranasal sinuses or the middle ear, or secondary to sepsis. Untreated congenital heart disease is a recognised risk factor. The site of abscess formation and the likely causative organism are both related to the source of infection (Box 27.81). Initial infection leads to local suppuration followed by loculation of pus within a surrounding wall of gliosis, which in a chronic abscess may form a tough capsule. Haematogenous spread may lead to multiple abscesses.

Clinical features

A cerebral abscess may present acutely with fever, headache, meningism and drowsiness, but more commonly presents over days or weeks as a cerebral mass lesion with little or no evidence of infection. Seizures, raised intracranial pressure and focal hemisphere signs occur alone or in combination. Distinction from a cerebral tumour may be impossible on clinical grounds.

Investigations

Lumbar puncture is potentially hazardous in the presence of raised intracranial pressure and CT should always precede it. CT reveals single

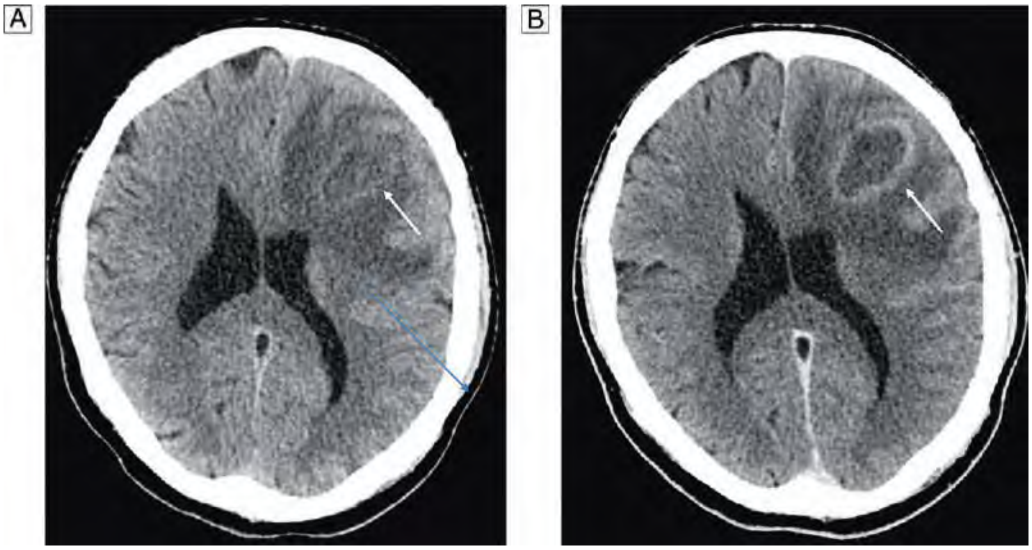


Fig. 27.49 Pre- A and post-contrast enhanced B images demonstrating a left frontal lobe abscess (arrows) with perilesional white matter oedema, localised mass effect and midline shift to the right.

27.81 Aetiology and treatment of bacterial cerebral abscess

Site of abscess	Source of infection	Likely organisms	Recommended treatment
Frontal lobe	Paranasal sinuses	Streptococci	Cefotaxime 2–3 g IV 4 times daily *plus* Metronidazole 500 mg IV 3 times daily
	Teeth	Anaerobes	
Temporal lobe	Middle ear	Streptococci Enterobacterales *Pseudomonas* species	Ampicillin 2–3 g IV 3 times daily *plus* Metronidazole 500 mg IV 3 times daily *plus either* Ceftazidime 2 g IV 3 times daily *or* Gentamicin* 5 mg/kg IV daily
Cerebellum	Sphenoid sinus	*Pseudomonas* species Anaerobes	
Any site	Penetrating trauma	Staphylococci *Clostridium* species	Vancomycin 15–20 mg/kg IV 2–3 times daily *plus* Metronidazole 500 mg IV 3 times daily
Multiple	Metastatic (bacteraemia or endocarditis) and cryptogenic	Streptococci Anaerobes Staphylococci	

*Monitor gentamicin levels.
(IV = intravenous)

or multiple low-density areas, which show ring enhancement with contrast and surrounding cerebral oedema (Fig. 27.49). There may be an elevated white blood cell count and ESR in patients with active local infection. The possibility of cerebral toxoplasmosis or tuberculous disease secondary to HIV infection should always be considered. MRI with diffusion weighted imaging may be helpful in distinguishing between cerebral abscess (hyperintense) and tumour (hypointense or variable increase lower than found in abscess).

Management and prognosis

Antimicrobial therapy is indicated once the diagnosis is made. The likely source of infection should guide the choice of antibiotic (see Box 27.81). Surgical drainage by burr-hole aspiration or excision may be necessary, especially where the presence of a capsule may lead to a persistent focus of infection. Epilepsy develops in around a third and is often resistant to treatment.

Despite advances in therapy, mortality remains 10%–20% and may partly relate to delay in diagnosis and treatment.

Lyme disease

Infection with *Borrelia burgdorferi* can cause numerous neurological problems, including polyradiculopathy, meningitis, encephalitis and mononeuritis multiplex.

Neurosyphilis

Neurosyphilis may present as an acute or chronic process and may involve the meninges, blood vessels and/or parenchyma of the brain and spinal cord. The incidence of syphilis continues to rise globally. The clinical manifestations are diverse and early diagnosis and treatment is essential.

Clinical features

The clinical and pathological features of the three most common presentations are summarised in Box 27.82. Neurological examination reveals signs indicative of the anatomical localisation of lesions. Delusions of grandeur suggest general paresis of the insane, but more commonly there is simply progressive dementia. Small and irregular pupils that react to convergence but not light, as described by Argyll Robertson (see Box 27.21), may accompany any neurosyphilitic syndrome, but most commonly tabes dorsalis (disease of the posterior columns and dorsal roots resulting in ataxia and lancinating pains) is present.

Investigations

Routine screening for syphilis is warranted in many neurological patients. Treponemal antibodies are positive in the serum in most patients, but CSF examination is essential if neurological involvement is suspected. Active disease is suggested by an elevated cell count, usually lymphocytic, and the protein content may be elevated to 0.5–1.0 g/L. Serological tests in CSF are usually positive, but progressive disease can occur with negative CSF serology.

Management

Aqueous crystalline penicillin G intravenously or intramuscular injection of procaine benzylpenicillin (procaine penicillin) and probenecid for 10–14 days is essential in the treatment of neurosyphilis of all types. Further

27.82 Clinical and pathological features of neurosyphilis

Type and interval from primary infection	Pathology	Clinical features
Meningovascular (5–12 years)*	Endarteritis obliterans Meningeal exudate (often basal meningitis) Granuloma (gumma)	Stroke Cranial nerve palsies Seizures/mass lesion
General paralysis of the insane (2–15 years)*	Degeneration in cerebral cortex/cerebral atrophy	Dementia Tremor Bilateral upper motor signs
	Thickened meninges	Delusions Paranoia
Tabes dorsalis (5–20 years)*	Degeneration of sensory neurons Wasting of dorsal columns Optic atrophy Trophic changes	Lightning pains Sensory ataxia Visual failure Abdominal crises Incontinence
Any of the above		Argyll Robertson pupils (see Box 27.21)

*All forms can occur earlier or later than noted.

courses of penicillin must be given if symptoms are not relieved, if the condition continues to advance or if the CSF continues to show signs of active disease. The cell count returns to normal within 3 months of completion of treatment, but the elevated protein takes longer to subside and some serological tests may never revert to normal. Evidence of clinical progression at any time is an indication for renewed treatment.

The spinal cord can be involved by other infections, including HTLV1, TB, schistosomiasis and echinococcus. For more detail on these conditions, please refer to Chapter 14.

Parenchymal parasitic infections

Neurocysticercosis

Neurocysticercosis is the commonest parasitic neurological disease globally. Most infections occur in low-resource regions, but it occurs in high-resource regions in travellers and immigrants. Cysts may be asymptomatic, often for years, or symptomatic, the symptoms depending on the site of the cysts. Seizures are the commonest manifestation. Parenchymal cysts occur in the brain or in the convexity sulci, while extraparenchymal cysts occur in the ventricles, cisterns and the spinal cord, and present most often with raised intracranial pressure. Investigation and management are discussed on p. 397.

Cerebral malaria

Cerebral malaria should be suspected in anyone presenting with fever, altered awareness or behaviour living in or returning from travel to a malaria endemic area. Drowsiness may progress over a few days, but coma can occur within hours. Level of consciousness may fluctuate and seizures occur, but focal neurological signs are unusual. The eyes frequently diverge with roving eye movements, but cranial nerve involvement and papilloedema are uncommon and suggest other causes, e.g. meningitis. Cerebral malaria is a serious condition with a case fatality rate of 15%–20% and requires rapid diagnosis and treatment (see Box 14.75).

Neuroschistosomiasis

Schistosomiasis is commonest in sub-Saharan Africa and neuroschistosomiasis should be considered in individuals in endemic areas and returning travellers presenting with neurological signs. The brain but more commonly spine (particularly conus medullaris) and cauda equina can be involved. Spinal cord involvement often results in a rapidly progressive transverse myelitis, leg pain, bladder and bowel involvement. Investigation and management are discussed on p. 394.

Parenchymal fungal infections

Fungal infections of brain parenchyma are uncommon but occur particularly in the immunocompromised, in the presence of intraventricular devices and as an extension of sinus infection.

Diseases caused by bacterial toxins

Tetanus

This disease results from infection with *Clostridium tetani*, a commensal in the gut of humans and domestic animals that is found in soil. Infection enters the body through wounds, which may be trivial. It is rare in the UK, occurring mostly in gardeners and farmers, but a recent increase has been seen in injection drug users. By contrast, the disease is common in many other countries, where dust contains spores derived from animal and human excreta. Unhygienic practices soon after birth may lead to infection of the umbilical stump or site of circumcision, causing tetanus neonatorum. Tetanus is still one of the major killers of adults, children and neonates in low-income countries, where the mortality rate can be nearly 100% in the newborn and around 40% in others.

In circumstances unfavourable to growth of the organism, spores are formed and these may remain dormant for years in the soil. Spores germinate and bacilli multiply only in the anaerobic conditions that occur in areas of tissue necrosis or if the oxygen tension is lowered by the presence of other organisms, particularly if aerobic. The bacilli remain localised but produce an exotoxin with an affinity for motor nerve endings and motor nerve cells.

The anterior horn cells and other spinal neurons including inhibitory interneurons are affected after the exotoxin has passed into the blood stream and their involvement results in rigidity and tonic muscle spasms. Symptoms first appear from 2 days to several weeks after injury: the shorter the incubation period, the more severe the attack and the worse the prognosis.

Clinical features

By far the most important early symptom is trismus – spasm of the masseter muscles, which causes difficulty in opening the mouth and in masticating; hence the name ‘lockjaw’. Lockjaw in tetanus is painless, unlike the spasm of the masseters due to dental abscess, septic throat or other causes. Conditions that can mimic tetanus include functional neurological disorders and phenothiazine overdosage, or overdose in injection drug users.

In tetanus, the tonic rigidity spreads to involve the muscles of the face, neck and trunk. Contraction of the frontalis and the muscles at the angles of the mouth leads to the so-called ‘risus sardonicus’. There is rigidity of the muscles at the neck and trunk of varying degree. The back is usually slightly arched (‘opisthotonus’) and there is a board-like abdominal wall.

In the more severe cases, violent spasms lasting for a few seconds to 3–4 minutes occur spontaneously, or may be induced by stimuli such as movement or noise. These episodes are painful and exhausting, and suggest a grave outlook, especially if they appear soon after the onset of symptoms. They gradually increase in frequency and severity for about 1 week and the patient may die from exhaustion, asphyxia or aspiration pneumonia. In less severe illness, periods of spasm may not commence until a week or so after the first sign of rigidity, and in very mild infections they may never appear. Autonomic involvement may cause cardiovascular complications, such as hypertension. Rarely, the only manifestation of the disease may be ‘local tetanus’ – stiffness or spasm of the muscles near the infected wound – and the prognosis is good if treatment is commenced at this stage.

Investigations

The diagnosis is made on clinical grounds. Laboratory testing supports the diagnosis, but treatment should not be delayed while waiting for results. Wound tissue samples or a wound swab may be sent in cooked meat broth for PCR and culture of *C. tetani*. Serum samples should be collected, before immunoglobulin is given, for tetanus toxin and antibodies against tetanus toxoid.

Management

Established disease

Management of established disease should begin as soon as possible, as shown in Box 27.83.

Prevention

Tetanus can be prevented by immunisation and prompt treatment of contaminated wounds by débridement and antibiotics. In patients with a contaminated wound, a 7- to 10-day course of metronidazole (500 mg intravenously every 6–8 hours) or penicillin G (2–4 million units every 4–6 hours) are recommended. Alternative antibiotics include tetracyclines, macrolides, clindamycin, cephalosporins and chloramphenicol. Tetanus toxoid containing vaccine and human tetanus immunoglobulin use should follow local guidelines, and depend on the level of risk associated with a wound, prior immunisation and time since last tetanus vaccination.

Botulism

Botulism is caused by the neurotoxins of *Clostridium botulinum*, which are extremely potent and cause disease after ingestion of even picogram amounts. Its classical form is an acute onset of bilateral cranial neuropathies associated with symmetric descending weakness.

Anaerobic conditions are necessary for the organism's growth. It may contaminate and thrive in many foodstuffs, where sealing and preserving provide the requisite conditions. Contaminated honey has been implicated in infant botulism, in which the organism colonises the gastrointestinal tract. Wound botulism is a growing problem in injection drug users.

The toxin causes predominantly bulbar and ocular palsies (difficulty in swallowing, blurred or double vision, ptosis), progressing to limb weakness and respiratory paralysis. Criteria for the clinical diagnosis are shown in Box 27.84.

27.83 Treatment of tetanus (consult local guidance)

Neutralise absorbed toxin

- Human tetanus antitoxin IM/IV (local guidance varies) or where human tetanus antitoxin is not available (e.g. in the UK), IVIG (human intravenous immunoglobulin) IV

Prevent further toxin production

- Débride wound
- Give metronidazole 500 mg IV every 6–8 hours ideally, or penicillin G 2–4 million units IV every 4–6 hours for 7–10 days

Control spasms

- Nurse in a quiet room
- Avoid unnecessary stimuli
- Give IV diazepam
- If spasms continue, paralyse patient and ventilate

General measures

- Maintain hydration and nutrition
- Treat secondary infections
- Vaccination following recovery

(IM = intramuscular; IV = intravenous)

Management includes assisted ventilation and general supportive measures until the toxin eventually dissociates from nerve endings 6–8 weeks following ingestion. A polyvalent antitoxin is available for post-exposure prophylaxis and for the treatment of suspected botulism. It specifically neutralises toxin types A, B and E and is not effective against infant botulism (in which active growth of the organism allows continued toxin production).

Prion diseases

Prions are unique amongst infectious agents in that they are devoid of any nucleic acid. They appear to be transmitted by acquisition of a normal mammalian protein (prion protein, PrP^{C}) that is in an abnormal conformation (PrP^{SC}, containing an excess of beta-sheet protein). The result is accumulation of protein that forms amyloid in the CNS, causing a transmissible spongiform encephalopathy (TSE) across several species.

Human prion diseases (Box 27.85) are characterised by the histopathological triad of cortical spongiform change, neuronal cell loss and gliosis. Associated with these changes there is deposition of amyloid, made up of an altered form of a normally occurring protein, the prion protein. Prion proteins are not inactivated by cooking or conventional sterilisation, and transmission is thought to occur by consumption of infected CNS tissue or by inoculation (e.g. via depth EEG electrodes, corneal grafts, cadaveric dura mater grafts and pooled cadaveric growth hormone preparations). The same diseases can occur in an inherited form, due to pathogenic variants in the *PrP* gene.

The apparent transmission of bovine spongiform encephalopathy (BSE) to humans was thought to be responsible for the emergence of a new variant of Creutzfeldt–Jakob disease (vCJD) in the UK (see below). This outbreak led to nationwide precautionary measures, such as

27.84 US Centers for Disease Control (CDC) definition of botulism

Three main syndromes

- Infantile
- Food-borne
- Wound infection

Clinical features

- Absence of fever
- Symmetrical neurological deficits
- Patient remains responsive
- Normal or slow heart rate and normal blood pressure
- No sensory deficits with the exception of blurred vision

27.85 Prion diseases affecting humans

Disease	Mechanism
Creutzfeldt–Jakob disease	
Sporadic	Unknown: spontaneous PrP^{C} to PrP^{SC} conversion or somatic mutation
Familial	Genetic: pathogenic variants in the *PrP* gene
Variant	Dietary ingestion: infection from bovine spongiform encephalopathy
Gerstmann–Sträussler–Scheinker disease	Genetic: pathogenic variants in the *PrP* gene
Fatal familial insomnia	Genetic: pathogenic variants in the *PrP* gene
Sporadic fatal insomnia	Genetic: spontaneous PrP^{C} to PrP^{SC} conversion or somatic mutation
Kuru	Dietary: ingestion of affected human brain

leucodepletion of all blood used for transfusion, and the mandatory use of disposable surgical instruments wherever possible for tonsillectomy, appendicectomy and ophthalmological procedures.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is the best-characterised human TSE. Some 10% of cases arise from a mutation in the gene coding for the prion protein. The sporadic form is the most common, occurring in middle-aged to older patients. Clinical features usually involve a rapidly progressive dementia, with myoclonus and a characteristic EEG pattern (repetitive slow-wave complexes), although a number of other features, such as visual disturbance or ataxia, may also be seen. These are particularly common in CJD transmitted by inoculation (e.g. by infected dura mater grafts). Death occurs after a mean of 4–6 months. There is no effective treatment.

Variant Creutzfeldt–Jakob disease

This type of CJD (vCJD) emerged in the late 1990s, affecting a small number of patients in the UK. The causative agent appears to be identical to that causing BSE in cows, and the disease may have been a result of the epidemic of BSE in the UK a decade earlier. Patients affected by vCJD are typically younger than those with sporadic CJD and present with neuropsychiatric changes and sensory symptoms in the limbs, followed by ataxia, dementia and death. Progression is slightly slower than in patients with sporadic CJD (mean time to death is over a year). Characteristic EEG changes are not present, but MRI brain scans show typical high-signal changes in the pulvinar thalami in a high proportion of cases (Fig. 27.50). Brain histology is distinct, with very florid plaques containing the prion proteins. Abnormal prion protein has been identified in tonsil specimens from patients with vCJD, leading to the suggestion that the disease could be transmitted by reticulo-endothelial tissue (like TSEs in animals but unlike sporadic CJD in humans). It was the emergence of this form of the disorder that led to the changes in public health and farming policy in the UK; while the incidence of vCJD has declined dramatically, surveillance and research continue.

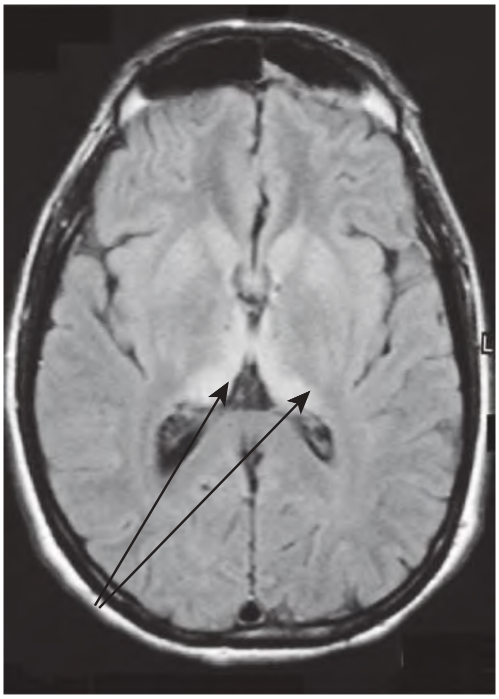

Fig. 27.50 Magnetic resonance imaging in variant Creutzfeldt–Jakob disease. Arrows indicate bilateral pulvinar hyperintensity.

Intracranial mass lesions and raised intracranial pressure

Many different types of mass lesion may arise within the intracranial cavity (Box 27.86). In low-income countries tuberculoma and other infections are frequent causes, but in the West intracranial haemorrhage and brain tumours are more common. The clinical features depend on the site of the mass, its nature and its rate of expansion. Symptoms and signs (see Box 27.87) are produced by a number of mechanisms.

Raised intracranial pressure

Raised intracranial pressure (RICP) may be caused by mass lesions, cerebral oedema, obstruction to CSF circulation leading to hydrocephalus, impaired CSF absorption and cerebral venous obstruction (see Box 27.86).

Clinical features

In adults, intracranial pressure is less than 10–15 mmHg. The features of RICP are listed in Box 27.87. The speed of pressure increase influences presentation. If it is slow, compensatory mechanisms may occur, including alteration in the volume of fluid in CSF spaces and venous sinuses, minimising symptoms. Rapid pressure increase (as in aggressive tumours) does not permit these compensatory mechanisms to take place, leading to early symptoms, including sudden death. Papilloedema is not always present, either because the pressure rise has been too rapid or because of anatomical anomalies of the meningeal sheath of the optic nerve.

A false localising sign is one in which the pathology is remote from the site of the expected lesion; in RICP, the 6th cranial nerve (unilateral or bilateral) is most commonly affected but the 3rd, 5th and 7th nerves may also be involved. Sixth nerve palsies are thought to be due either to stretching of the long slender nerve or to compression against the petrous temporal bone ridge. Transtentorial herniation of the uncus may

27.86 Common causes of raised intracranial pressure

Mass lesions

- Intracranial haemorrhage (traumatic or spontaneous):
  - Extradural haematoma
  - Subdural haematoma
  - Intracerebral haemorrhage
- Cerebral tumour (particularly posterior fossa lesions or high-grade gliomas: see Box 27.88)
- Infective:
  - Cerebral abscess
  - Tuberculoma
  - Cysticercosis
  - Hydatid cyst
- Colloid cyst (in ventricles)

Disturbance of cerebrospinal fluid circulation

- Obstructive (non-communicating) hydrocephalus: obstruction within ventricular system
- Communicating hydrocephalus: site of obstruction outside ventricular system

Obstruction to venous sinuses

- Cerebral venous thrombosis
- Trauma (depressed fractures overlying sinuses)

Diffuse brain oedema or swelling

- Meningo-encephalitis
- Trauma (diffuse head injury, near-drowning)
- Subarachnoid haemorrhage
- Metabolic (e.g. water intoxication)
- Idiopathic intracranial hypertension

27.87 Clinical features of intracranial mass lesions

Presentation	Features
Seizures	Focal onset ± generalised spread
Focal symptoms	Progressive loss of function Weakness Numbness Dysphasia Cranial neuropathy
False localising signs	Unilateral/bilateral 6th nerve palsies Contralateral 3rd nerve (usually pupil first)
Raised intracranial pressure (usually aggressive tumours causing vasogenic oedema or obstructive hydrocephalus)	Headache worse on lying/straining Vomiting Diplopia (6th nerve involvement) Papilloedema Bradycardia, raised blood pressure Impaired conscious level
Stroke/TIA-like symptoms	Acute haemorrhage into tumour Paroxysmal 'tumour attacks'
Cognitive/behavioural change	Usually frontal mass lesions
Endocrine abnormalities	Pituitary tumours
Incidental finding	Asymptomatic but identified on imaging (meningiomas commonly)

(TIA = transient ischaemic attack)

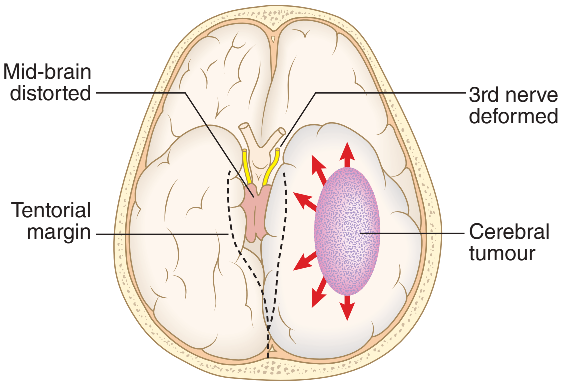

Fig. 27.51 **Cerebral tumour displacing medial temporal lobe and causing pressure on the mid-brain and 3rd cranial nerve.**

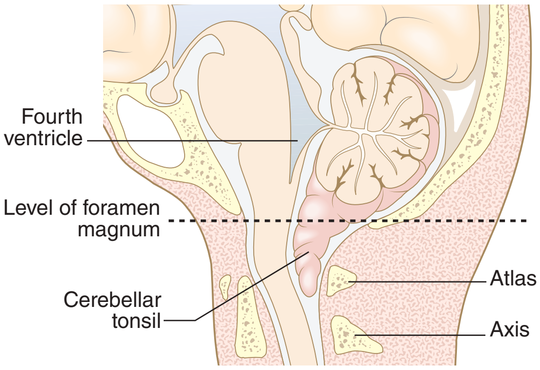

Fig. 27.52 **Tonsillar cone.** Downward displacement of the cerebellar tonsils below the level of the foramen magnum.

27.88 Primary brain tumours

Histological type	Common site	Age
Malignant		
Glioma (astrocytoma)	Cerebral hemisphere	Adulthood
	Cerebellum	Childhood/adulthood
	Brainstem	Childhood/young adulthood
Oligodendroglioma	Cerebral hemisphere	Adulthood
Medulloblastoma	Posterior fossa	Childhood
Ependymoma	Posterior fossa	Childhood/adolescence
Cerebral lymphoma	Cerebral hemisphere	Adulthood
Benign		
Meningioma	Cortical dura Parasagittal Sphenoid ridge Suprasellar Olfactory groove	Adulthood (often incidental finding)
Neurofibroma	Acoustic neuroma	Adulthood
Craniopharyngioma	Suprasellar	Childhood/adolescence
Pituitary adenoma	Pituitary fossa	Adulthood
Colloid cyst	Third ventricle	Any age
Pineal tumours	Quadrigeminal cistern	Childhood (teratomas) Young adulthood (germ cell)

compress the ipsilateral 3rd nerve and usually involves the pupillary fibres first, causing a dilated pupil; however, a false localising contralateral 3rd nerve palsy may also occur, perhaps due to extrinsic compression by the tentorial margin. Vomiting, coma, bradycardia and arterial hypertension are later features of RICP.

The rise in intracranial pressure from a mass lesion may cause displacement of the brain. Downward displacement of the medial temporal lobe (uncus) through the tentorium due to a large hemisphere mass may cause 'temporal coning' (Fig. 27.51). This may stretch the 3rd and/or 6th cranial nerves or cause pressure on the contralateral cerebral peduncle (giving rise to ipsilateral upper motor neuron signs) and is usually accompanied by progressive coma. Downward movement of the cerebellar tonsils through the foramen magnum may compress the medulla – 'tonsillar coning' (Fig. 27.52). This may result in brainstem haemorrhage and/or acute obstruction of the CSF pathways. As coning progresses, coma and death occur unless the condition is rapidly treated.

Management

Primary management of RICP should be targeted at relieving the cause (e.g. surgical decompression of mass lesion, glucocorticoids to reduce vasogenic oedema or shunt procedure to relieve hydrocephalus). Supportive treatment includes maintenance of fluid balance, blood pressure control, head elevation and use of diuretics such as mannitol. Intensive care support may be needed.

Brain tumours

Primary brain tumours are a heterogeneous collection of neoplasms arising from the brain tissue or meninges and vary from benign to highly malignant. Primary malignant brain tumours (Box 27.88) are rare, accounting for 1% of all adult tumours but a higher proportion in children. The most common benign brain tumour is a meningioma. Primary brain tumours do not metastasise due to the absence of lymphatic drainage in the brain. There are rare pathological subtypes, however, such as medulloblastoma, which do have a propensity to metastasise; the reasons for this are not clear. Most cerebral tumours are sporadic but may be associated with genetic syndromes such as neurofibromatosis or tuberous sclerosis. Brain tumours are not classified by the usual TNM system but by the World Health Organization (WHO) grading I–IV; this is based on histology (e.g. nuclear pleomorphism, presence of mitoses and presence

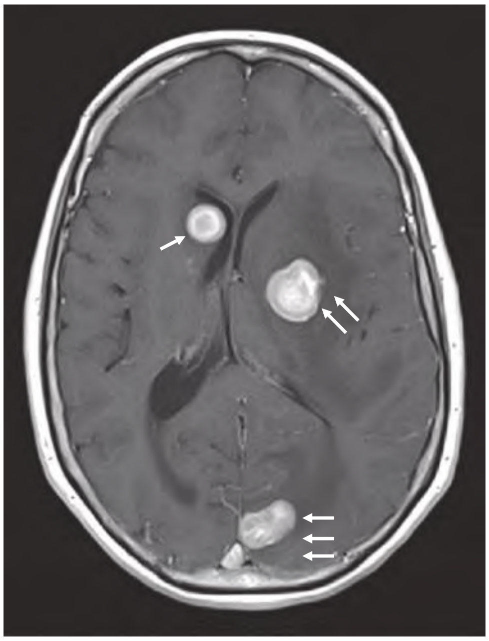

Fig. 27.53 **Post-contrast MRI head showing bilateral metastases involving the right caudate nucleus (single arrow), left basal ganglia (double arrow) and the left occipital lobe (triple arrow) in a patient with lung cancer.** The left basal ganglia lesion is associated with perilesional white matter oedema and localised mass effect and midline shift to the right.

of necrosis), with grade I the most benign and grade IV the most malignant. Gliomas account for 60% of brain tumours, with the aggressive glioblastoma multiforme (WHO grade IV) the most common glioma, followed by meningiomas (20%) and pituitary tumours (10%). Although the lower-grade gliomas (I and II) may be very indolent, with prognosis measured in terms of many years, these may transform to higher-grade disease at any time, with a resultant sharp decline in life expectancy.

Most malignant brain tumours are due to metastases, with intracranial metastases complicating about 20% of extracranial malignancies. The rate is higher with primaries in the bronchus, breast and gastrointestinal tract (Fig. 27.53). Metastases usually occur in the white matter of the cerebral or cerebellar hemispheres, but there are diffuse leptomeningeal types.

Clinical features

The presentation is variable and usually influenced by the rate of growth. High-grade disease (WHO grades III and IV) tends to present with a short (weeks) history of mass effect (headache, nausea secondary to RICP), while more indolent tumours can present with slowly progressive focal neurological deficits, depending on their location (see Box 27.87); generalised or focal seizures are common in either. Headache, if present, is usually accompanied by focal deficits or seizures, and isolated stable headache is almost never due to intracranial tumour.

The size of the primary tumour is of far less prognostic significance than its location within the brain. Tumours within the brainstem will result in early neurological deficits, while those in the frontal region may be quite large before symptoms occur.

Investigations

Diagnosis is by neuroimaging (Figs. 27.54 and 27.55) and pathological grading following biopsy or resection where possible. The more malignant tumours are more likely to demonstrate contrast enhancement on imaging. If the tumour appears metastatic, further investigation to find the primary is required.

Management

Brain tumours are treated with a combination of surgery, radiotherapy and chemotherapy, depending on the type of tumour and the patient.

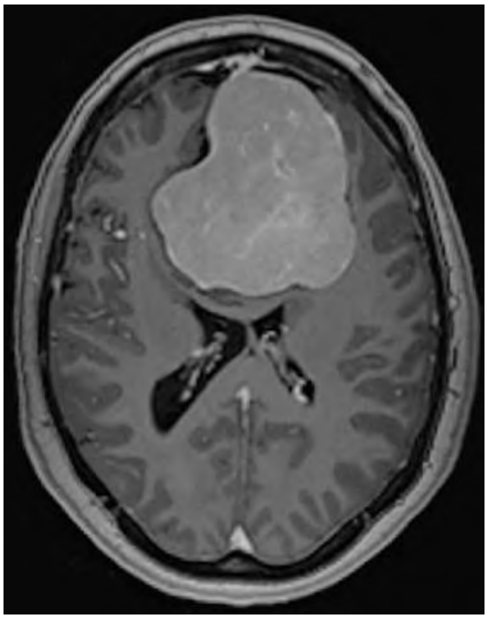

Fig. 27.54 **Post-contrast axial MRI image demonstrating a large left enhancing parafalcine meningioma with significant local mass effect compressing and displacing the lateral ventricles posteriorly.**

Advancing age is the most powerful negative prognostic factor in CNS tumours, so best supportive care (including glucocorticoid therapy) may be most appropriate in older patients with metastases or high-grade disease. Treatment may not always be indicated in low-grade gliomas and watchful waiting may be appropriate, although a more aggressive approach is increasingly favoured.

Dexamethasone given orally (or intravenously where RICP is acutely or severely raised) may reduce the vasogenic oedema typically associated with metastases and high-grade gliomas.

Prolactin- or growth hormone–secreting pituitary adenomas may respond well to treatment with dopamine agonists (such as bromocriptine, cabergoline or quinagolide); in this situation, imaging and hormone levels may be all that is required to establish a formal diagnosis, precluding the need for surgery.

Surgical

The mainstay of primary treatment is surgery, either resection (full or partial debulking) or biopsy, depending on the site and likely radiological diagnosis. Clearly, if a tumour occurs in an area of brain that is highly important for normal function (e.g. motor strip), then biopsy may be the only safe surgical intervention but, in general, maximal safe resection is the optimal surgical management. Meningiomas and acoustic neuromas offer the best prospects for complete removal and thus cure. Some meningiomas can recur, however, particularly those of the sphenoid ridge, when partial excision is often all that is possible. Thereafter, post-operative surveillance may be required, as radiotherapy is effective at preventing further growth of residual tumour. Pituitary adenomas may be removed by a trans-sphenoidal route, avoiding the need for a craniotomy. Unfortunately, gliomas, which account for the majority of brain tumours, cannot be completely excised, since infiltration spreads well beyond the apparent radiological boundaries of the intracranial mass. Recurrence is therefore the rule, even if the mass of the tumour is apparently removed completely; partial excision ('debulking') may be useful in alleviating symptoms caused by RICP, but although there is increasing evidence that the degree of surgical excision may have a positive influence on survival, this has not yet been convincingly demonstrated.

Radiotherapy and chemotherapy

In the majority of primary CNS tumours, radiation and chemotherapy are used to control disease and extend survival rather than for cure.

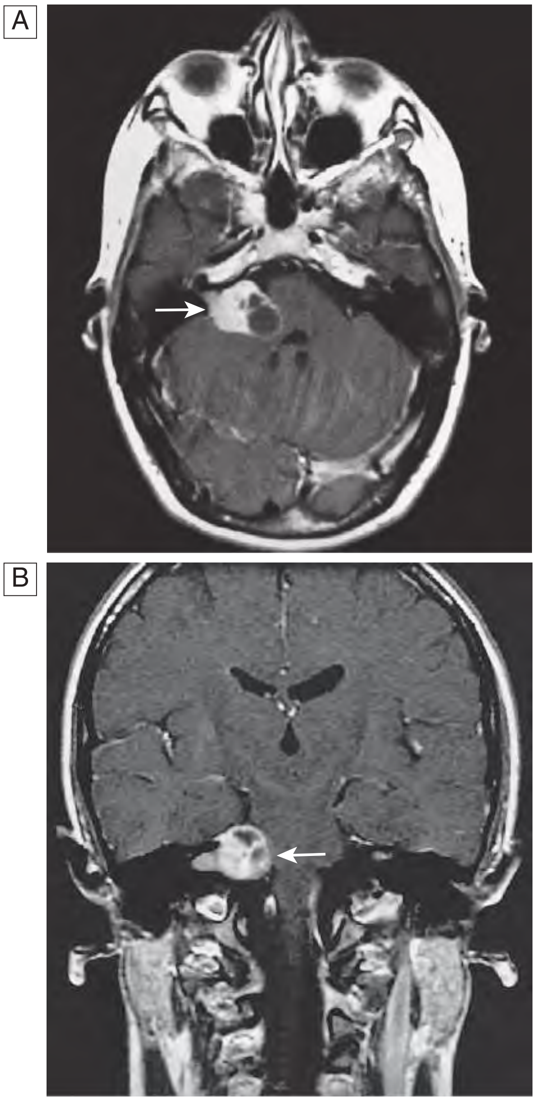

Fig. 27.55 **Magnetic resonance image of an acoustic neuroma (arrows) in the posterior fossa compressing the brainstem.** A Axial image. B Coronal image.

Meningioma and pituitary adenoma offer the best chance of life-long remission. The gliomas are incurable; high-grade, WHO grade IV disease still carries a median survival of just over 1 year. In this situation, patient and family should always be involved in decisions regarding treatment. The diagnosis, and often the symptoms, are devastating, and support from palliative care and social work is crucial at an early stage. In WHO grade III disease, prognosis is a little better (2–4 years), and in rarer, more indolent tumours, very prolonged survival is possible.

Advances have been made recently in terms of therapeutic outcome. Standard care for WHO grade IV glioblastoma multiforme is now combination radiotherapy with temozolomide chemotherapy; although this improves median survival of the population from only 12 to 14.5 months, up to 25% of patients survive for more than 2 years (compared to approximately 10% with radiotherapy alone). Ten percent will survive more than 5 years with temozolomide (virtually unheard of with radiotherapy alone). Benefits are more likely in well-debulked patients who are younger and fitter. Implantation of chemotherapy gives a small survival benefit.

Understanding of the molecular biology of brain tumours has allowed the use of biomarkers to guide therapy and prognostic discussions. In patients with methylation of the promoter region of the *MGMT* (methyl guanine methyl transferase) gene (about 30% of the population) within the tumour, 2-year survival is almost 50%. MGMT reduces the cytotoxicity of temozolomide, and this mutation also reduces the enzyme's activity, rendering the tumour more sensitive to chemotherapy. In grade II and III gliomas, the presence of the loss of heterozygosity (LOH) 1p19q chromosomal abnormality confers chemosensitivity and thus improves prognosis. The presence of a rare mutation in the *IDH-1* (isocitrate dehydrogenase) gene confers a more favourable prognosis in patients with glioblastoma.

There is a small group of highly malignant grade IV tumours that can be cured with aggressive therapy. Medulloblastomas have a good chance of long-term remission with maximal surgery followed by irradiation of the whole brain and spine; younger patients may also benefit from concomitant and adjuvant chemotherapy. Older patients do not tolerate this, however.

Once tumours relapse, chemotherapy response rates are low and survival is short in high-grade disease. In the more uncommon low-grade tumours, repeated courses of chemotherapy can result in much more prolonged survival.

In metastatic disease, radiotherapy offers a modest improvement in survival but with costs in terms of quality of life; treatment therefore needs careful discussion with the patient. Benefits may be superior in breast cancer but there is little to separate other pathologies. Occasional chemosensitive cancers, such as small-cell lung cancer, may benefit from systemic chemotherapy but intracerebral metastases represent a late stage of disease and have a short prognosis.

Prognosis

The WHO histological grading system is a powerful predictor of prognosis in primary CNS tumours, though it does not yet take account of individual biomarkers. For each tumour type and grade, advancing age and deteriorating functional status are the next most important negative prognostic features. The overall 5-year survival rate of about 14% in adults masks a wide variation that depends on tumour type.

Acoustic neuroma

This is a benign tumour of Schwann cells of the 8th cranial nerve, which may arise in isolation or as part of neurofibromatosis type 2 (see below). When sporadic, acoustic neuroma occurs after the third decade and is more frequent in females. The tumour commonly arises near the nerve's entry point into the medulla or in the internal auditory meatus, usually on the vestibular division. Acoustic neuromas account for 80%–90% of tumours at the cerebellopontine angle.

Clinical features

Acoustic neuroma typically presents with unilateral progressive hearing loss, sometimes with tinnitus. Vertigo is an unusual symptom, as slow growth allows compensatory brainstem mechanisms to develop. In some cases, progressive enlargement leads to distortion of the brainstem and/or cerebellar peduncle, causing ataxia and/or cerebellar signs in the limbs. Distortion of the fourth ventricle and cerebral aqueduct may cause hydrocephalus (see below), which may be the presenting feature. Facial weakness is unusual at presentation, but facial palsy may follow surgical removal of the tumour. The tumour may be identified incidentally on cranial imaging.

Investigations

MRI is the investigation of choice (see Fig. 27.55).

Management

Surgery is the treatment of choice. If the tumour can be completely removed, the prognosis is excellent, although deafness is a common complication of surgery. Stereotactic radiosurgery (radiotherapy) may be appropriate for some lesions.

Neurofibromatosis

Neurofibromatosis encompasses two clinically and genetically separate conditions, with an autosomal dominant pattern of inheritance. The more common neurofibromatosis type 1 (NF1) is caused by pathogenic variants in the *NF1* gene on chromosome 17, half of which are new pathogenic variants. NF1 is characterised by neurofibromas (benign peripheral nerve sheath tumours) and skin involvement (Fig. 27.56), and may

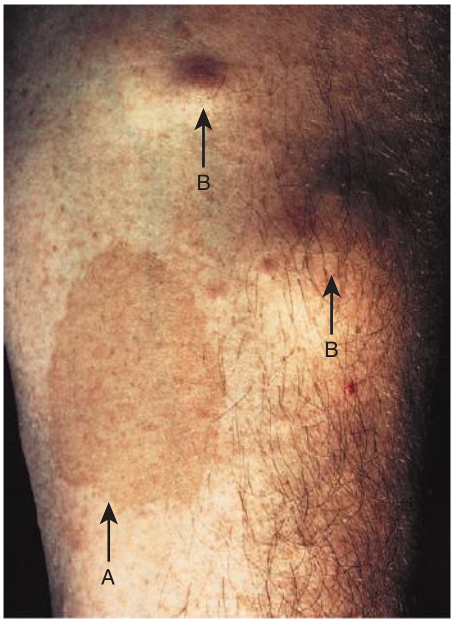

Fig. 27.56 **A café au lait spot (arrow A) and subcutaneous nodules (arrows B) on the forearm of a patient with neurofibromatosis type 1.**

affect numerous systems (Box 27.89). Neurofibromatosis type 2 (NF2) is caused by pathogenic variants of the *NF2* gene on chromosome 22 and is characterised by schwannomas (benign peripheral nerve sheath tumours comprising Schwann cells only) with little skin involvement; the clinical manifestations are more restricted to the eye and nervous system (see Box 27.89). Malignant change may occur in NF1 neurofibromas but is rare in NF2 schwannomas. The prevalence of NF1 and NF2 is about 20–50 per 100 000 and 1.5 per 100 000, respectively.

Von Hippel–Lindau disease

This rare autosomal dominant disease is caused by pathogenic variants of the *VHL* tumour suppressor gene on chromosome 3. It promotes development of tumours affecting the kidney, adrenal gland, CNS, eye, inner ear, epididymis and pancreas, which may undergo malignant change. Benign haemangiomas and haemangioblastomas affect about 80% of patients and are mostly cerebellar and retinal.

Paraneoplastic neurological disease

Paraneoplastic neurological syndromes often present before the underlying tumour declares itself and cause considerable disability. They are discussed in full on page 1209.

Hydrocephalus

Hydrocephalus is the excessive accumulation of CSF within the brain, and may be caused either by increased CSF production, by reduced CSF absorption or by obstruction of the circulation (Fig. 27.57). Symptoms range from none to sudden death, depending on the speed at which and degree to which hydrocephalus develops. The causes are listed in Box 27.90. The terms ‘communicating’ and ‘non-communicating’ (also known as obstructive) hydrocephalus refer to blockage either outside or within the ventricular system, respectively (Fig. 27.58).

Normal pressure hydrocephalus

Normal pressure hydrocephalus (NPH) is a controversial entity, said to involve intermittent rises in CSF pressure, particularly at night. It is described in old age as being associated with a triad of gait apraxia, dementia and urinary incontinence.

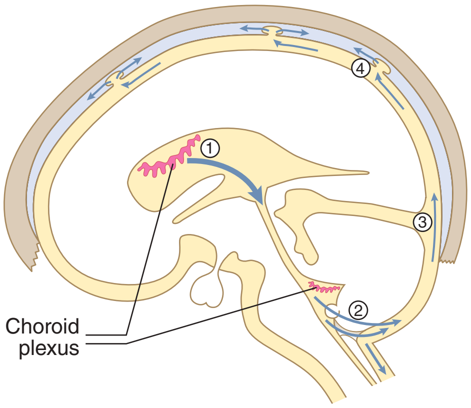

Fig. 27.57 **The circulation of cerebrospinal fluid (CSF).** (1) CSF is synthesised in the choroid plexus of the ventricles and flows from the lateral and third ventricles through the aqueduct to the fourth ventricle. (2) At the foramina of Luschka and Magendie it exits the brain, flowing over the hemispheres (3) and down around the spinal cord and roots in the subarachnoid space. (4) It is then absorbed into the dural venous sinuses via the arachnoid villi.

Management

Diversion of the CSF by means of a shunt placed between the ventricular system and the peritoneal cavity or right atrium may result in rapid relief of symptoms in obstructive hydrocephalus. The outcome of shunting in NPH is much less predictable and, until a good response can be predicted, the management of individual cases will remain uncertain.

Idiopathic intracranial hypertension

This usually occurs in young women with high BMI. The annual incidence is about 3 per 100 000. RICP occurs in the absence of a structural lesion, hydrocephalus or other identifiable cause. The aetiology is uncertain but there is an association with obesity in females, perhaps inducing a defect of CSF reabsorption by the arachnoid villi. A number of drugs may be associated, including tetracycline, vitamin A and retinoid derivatives.

Clinical features

The usual presentation is with headache, sometimes accompanied by diplopia and visual disturbance (most commonly, transient obscurations of vision associated with changes in posture). Clinical examination reveals papilloedema but little else. False localising cranial nerve palsies (usually of the 6th nerve) may be present. It is important to record visual fields accurately for future monitoring.

Investigations

Brain imaging is required to exclude a structural or other cause (e.g. cerebral venous sinus thrombosis). The ventricles are typically normal in size or small ('slit' ventricles). The diagnosis may be confirmed by lumbar puncture, which shows raised normal CSF constituents at increased pressure (usually > 25 cmH_2O CSF).

Management

Management can be difficult. Weight loss in overweight patients may be helpful and patients with a BMI > 30 kg/m^2 should be counselled about weight management. Acetazolamide or topiramate may help to lower intracranial pressure, the latter perhaps aiding weight loss in some patients (note both drugs are teratogenic). Repeated lumbar punctures are not recommended other than as a temporary vision sparing measure prior to CSF diversion, as CSF reaccumulates rapidly and lumbar punctures can uncommonly cause side-effects. Patients failing to respond, in whom chronic papilloedema threatens vision, may require optic nerve sheath fenestration or a lumbo-peritoneal shunt.

27.90 Causes of hydrocephalus

Congenital malformations

- Aqueduct stenosis
- Chiari malformations
- Dandy–Walker syndrome
- Benign intracranial cysts
- Vein of Galen aneurysms
- Congenital central nervous system infections
- Craniofacial anomalies

Acquired causes

- Mass lesions (especially those in the posterior fossa)
- Tumour
- Colloid cyst of third ventricle
- Abscess
- Haematoma
- Absorption blockages due to:
  - Inflammation (e.g. meningitis, sarcoidosis)
  - Intracranial haemorrhage

Head injury

Diagnosis of head trauma is usually clear either from the history or from signs of external trauma to the head. Brain injury is more likely with skull fracture but can occur without. Individual cranial nerves may be damaged in fractures of the facial bones or skull base. Intracranial effects can be substantial and take several forms: extradural haematoma (collection of blood between the skull and dura); subdural haematoma (collection of blood between the dura and the surface of the brain); intracerebral haematoma; or diffuse axonal injury.

Whatever pathology occurs, the resultant RICP may lead to coning (see Figs. 27.51 and 27.52). Haematomas are identified by CT and management is by surgical drainage, usually via a burr hole. Penetrating skull fractures lead to increased infection risk. Long-term sequelae include headache, cognitive decline and depression, all contributing to significant social, work, personality and family difficulties.

Subdural haematoma may occur spontaneously, particularly in patients on anticoagulants, in old age and with alcohol misuse. There may or may not be a history of trauma. Patients present with subacute impairment of brain function, both globally (obtundation and coma) and focally (hemiparesis, seizures). Headache may not be present. The diagnosis should always be considered in those who present with reduced conscious level.

Beyond the immediate consequences of brain injury, there is increasing suspicion of long-term consequences, including dementia, postulated after either single (moderate or severe) injuries or even after multiple mild injuries, such as in boxers. If substantiated, this would encourage more effort to go into prevention of repeated brain injury in sporting contexts.

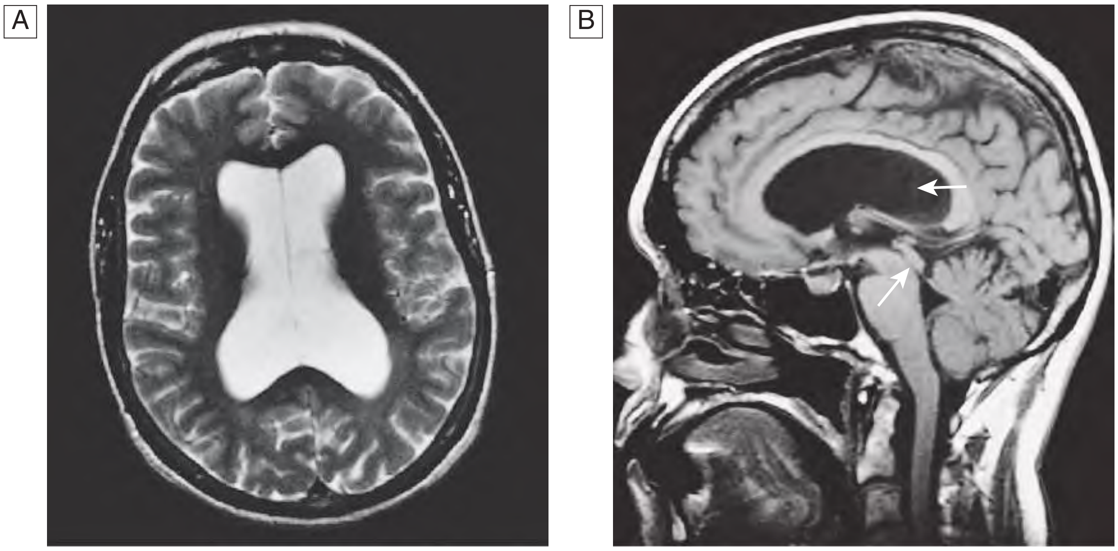

Fig. 27.58 Magnetic resonance image of hydrocephalus due to aqueduct stenosis. **A** Axial T2-weighted image (cerebrospinal fluid appears white): note the dilated lateral ventricles. **B** Sagittal T1-weighted image (cerebrospinal fluid appears black): note the dilated ventricles (top arrow) and narrowed aqueduct (bottom arrow).

Disorders of cerebellar function

Cerebellar dysfunction can manifest as incoordination of limb function, gait ataxia, speech or eye movements. Acute dysfunction may be caused by alcohol or prescription drugs (especially the sodium channel-blocking antiseizure medications phenytoin and carbamazepine).

Inflammatory changes in the cerebellum may cause symptoms in the aftermath of some infections (especially herpes zoster) or as a paraneoplastic phenomenon. The hereditary spinocerebellar ataxias are described on page 1213; they manifest as progressive ataxias in middle and old age, often with other neurological features that aid specific diagnosis.

Disorders of the spine and spinal cord

The spinal cord and spinal roots may be affected by intrinsic disease or by disorders of the surrounding meninges and bones. The clinical presentation of these conditions depends on the anatomical level at which the cord or roots are affected, as well as the nature of the pathological process involved. It is important to recognise when the spinal cord is at risk of compression so that urgent action can be taken.

Cervical spondylosis

Cervical spondylosis is the result of osteoarthritis in the cervical spine. It is characterised by degeneration of the intervertebral discs and osteophyte formation. Such 'wear and tear' is extremely common and radiological changes are frequently found in asymptomatic individuals over the age of 50. Spondylosis may be associated with neurological dysfunction. In order of frequency, the C5/6, C6/7 and C4/5 vertebral levels affect C6, C7 and C5 roots, respectively (Fig. 27.59).

Cervical radiculopathy

Acute onset of compression of a nerve root occurs when a disc prolapses laterally. More gradual onset may be due to osteophytic encroachment of the intervertebral foramina.

Clinical features

The patient complains of pain in the neck that may radiate in the distribution of the affected nerve root. The neck is held rigidly and neck movements may exacerbate pain. Paraesthesia and sensory loss may be found in the affected segment and there may be lower motor neuron signs, including weakness, wasting and reflex impairment (Fig. 27.60).

Investigations

Where there is no trauma, imaging should not be carried out for isolated cervical pain. MRI is the investigation of choice in those with radicular symptoms. X-rays offer limited benefit, except in excluding destructive lesions, and electrophysiological studies rarely add to clinical examination with MRI.

Management

Conservative treatment with analgesics and physiotherapy results in resolution of symptoms in the great majority of patients, but a few require surgery in the form of discectomy or radicular decompression.

Fig. 27.60 Findings in cervical nerve root compression.

Cervical myelopathy

Dorsomedial herniation of a disc and the development of transverse bony bars or posterior osteophytes may result in pressure on the spinal cord or the anterior spinal artery, which supplies the anterior two-thirds of the cord (see Fig. 27.59).

Clinical features

The onset is usually insidious and painless but acute deterioration may occur after trauma, especially hyperextension injury. Upper motor neuron signs develop in the limbs, with spasticity of the legs usually appearing before the arms are involved. Sensory loss in the upper limbs is common, producing tingling, numbness and proprioception loss in the hands, with progressive clumsiness. Sensory manifestations in the legs are much less common. Neurological deficit usually progresses gradually and disturbance of micturition is a very late feature.

Investigations

MRI (see Fig. 27.59), or rarely myelography, will direct surgical intervention. The former provides information on the state of the spinal cord at the level of compression.

Management

Surgical procedures, including laminectomy and anterior discectomy, may arrest progression of disability but neurological improvement is not the rule. The decision as to whether surgery should be undertaken may be difficult. Manual manipulation of the cervical spine is of no proven benefit and may precipitate acute neurological deterioration.

Prognosis

The prognosis of cervical myelopathy is variable. In many patients, the condition stabilises or even improves without intervention. If progression results in sphincter dysfunction or pyramidal signs, surgical decompression should be considered.

Lumbar spondylosis

This term covers degenerative disc disease and osteoarthritic change in the lumbar spine. Pain in the distribution of the lumbar or sacral roots ('sciatica') is almost always due to disc protrusion but can be a feature of other rare but important disorders, including spinal tumour, malignant disease in the pelvis and tuberculosis of the vertebral bodies.

Lumbar disc herniation

While acute lumbar disc herniation is often precipitated by trauma (usually lifting heavy weights while the spine is flexed), genetic factors may also be important. The nucleus pulposus may bulge or rupture through the annulus fibrosus, giving rise to pressure on nerve endings in the spinal ligaments, changes in the vertebral joints or pressure on nerve roots.

Pathophysiology

The altered mechanics of the lumbar spine result in loss of lumbar lordosis and there may be spasm of the paraspinal musculature. Root pressure is suggested by limitation of flexion of the hip on the affected side if the straight leg is raised (Lasègue sign). If the third or fourth lumbar root is involved, the Lasègue sign may be negative, but pain in the back may be induced by hyperextension of the hip (femoral nerve stretch test). The roots most frequently affected are S1, L5 and L4; the signs of root pressure at these levels are summarised in Figure 27.61.

Clinical features

The onset may be sudden or gradual. Alternatively, repeated episodes of low back pain may precede sciatica by months or years. Constant aching pain is felt in the lumbar region and may radiate to the buttock, thigh, calf and foot. Pain is exacerbated by coughing or straining but may be relieved by lying flat.

Investigations

MRI is the investigation of choice if available, since soft tissues are well imaged. Plain X-rays of the lumbar spine are of little value in the diagnosis of disc disease, although they may demonstrate conditions affecting the vertebral body. CT can provide helpful images of the disc protrusion and/or narrowing of exit foramina.

Management

Some 90% of patients with sciatica recover following conservative treatment with analgesia and early mobilisation; bed rest does not help recovery. The patient should be instructed in back-strengthening exercises and advised to avoid physical manoeuvres likely to strain the lumbar spine. Injections of local anaesthetic or glucocorticoids may be useful adjunctive treatment if symptoms are due to ligamentous injury or joint dysfunction. Surgery may have to be considered if there is no response to conservative treatment or if progressive neurological deficits develop. Central disc prolapse with bilateral symptoms and signs and disturbance of sphincter function requires urgent surgical decompression.

Lumbar canal stenosis

This occurs with a congenitally narrowed lumbar spinal canal, exacerbated by the degenerative changes that commonly occur with age.

Pathophysiology

The symptoms of spinal stenosis are thought to be due to local vascular compromise secondary to the canal stenosis, rendering the nerve roots ischaemic and intolerant of the increased demand that occurs on exercise.

Disc level	L3/L4	L4/L5	L5/S1
Root	L4	L5	S1
Sensory loss (see Fig. 27.10)			Muscle weakness	Knee extension	Ankle dorsiflexion Ankle inversion	Plantar flexion
Reflex loss ●	Knee	None	Ankle

Fig. 27.61 Findings in lumbar nerve root compression.

Clinical features

Patients, who are usually in old age, develop exercise-induced weakness and paraesthesia in the legs ('spinal claudication'). These symptoms progress with continued exertion, often to the point that the patient can no longer walk, but are quickly relieved by a short period of rest. Physical examination at rest shows preservation of peripheral pulses with absent ankle reflexes. Weakness or sensory loss may only be apparent if the patient is examined immediately after exercise.

Investigations

The investigation of first choice is MRI, but contraindications (body habitus, metallic implants) may make CT or myelography necessary.

Management

Lumbar laminectomy may provide relief of symptoms and recovery of normal exercise tolerance.

Spinal cord compression

Spinal cord compression is one of the more common neurological emergencies encountered in clinical practice and the usual causes are listed in Box 27.91. A space-occupying lesion within the spinal canal may damage nerve tissue either directly by pressure or indirectly by interference with blood supply. Oedema from venous obstruction impairs neuronal function, and ischaemia from arterial obstruction may lead to necrosis of the spinal cord. The early stages of damage are reversible but severely damaged neurons do not recover, hence the importance of early diagnosis and treatment.

27.91 Causes of spinal cord compression

Site	Frequency	Causes
Vertebral	80%	Trauma (extradural) Intervertebral disc prolapse Metastatic carcinoma (e.g. breast, prostate, bronchus) Myeloma Tuberculosis
Meninges (intradural, extramedullary)	15%	Tumours (e.g. meningioma, neurofibroma, ependymoma, metastasis, lymphoma, leukaemia) Epidural abscess
Spinal cord (intradural, intramedullary)	5%	Tumours (e.g. glioma, ependymoma, metastasis)

Clinical features

The onset of symptoms of spinal cord compression is usually slow (over weeks) but can be acute as a result of trauma or metastases (Figs. 27.62 and 27.63; see Fig. 27.59), especially if there is associated arterial occlusion. The symptoms are shown in Box 27.92.

Pain and sensory symptoms occur early, while weakness and sphincter dysfunction are usually late manifestations. The signs vary according to the level of the cord compression and the structures involved. There may be tenderness to percussion over the spine if there is vertebral disease and this may be associated with a local kyphosis. Involvement of the roots at the level of the compression may cause dermatomal sensory impairment and corresponding lower motor signs. Interruption of fibres

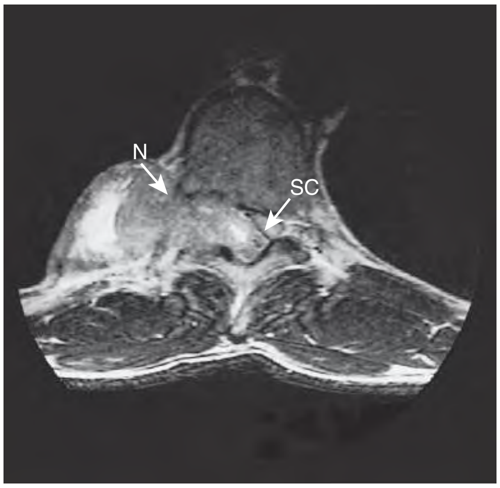

Fig. 27.62 Axial magnetic resonance image of thoracic spine. A neurofibroma (N) is compressing the spinal cord (SC) and emerging in a 'dumbbell' fashion through the vertebral foramen into the paraspinal space.

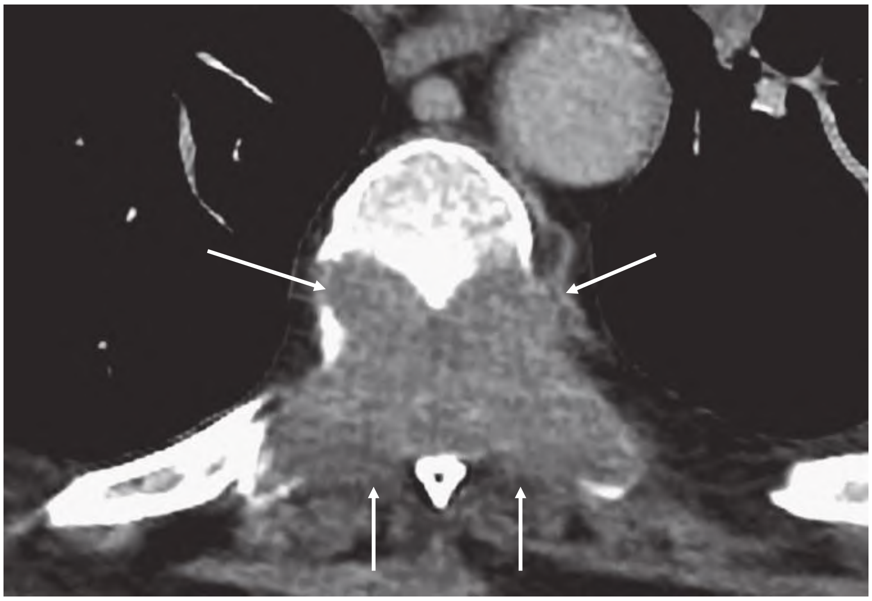

Fig. 27.63 CT scan demonstrating a metastasis infiltrating the body and the posterior elements of the T8 vertebral body (arrows) extending into the spinal canal with invasion of the spinal cord.

in the spinal cord causes sensory loss and upper motor neuron signs below the level of the lesion, and there is often disturbance of sphincter function. The distribution of these signs varies with the level of the lesion (Box 27.93).

The Brown–Séquard syndrome (see Fig. 27.22E) results if damage is confined to one side of the cord; the findings are explained by the anatomy of the sensory tracts (see Fig. 27.11). With compressive lesions, there is usually a band of pain at the level of the lesion in the distribution of the nerve roots subject to compression.

Investigations

Patients with a history of acute or subacute spinal cord syndrome should be investigated urgently, as listed in Box 27.94. The investigation of choice is MRI (see Fig. 27.62), as it can define the extent of compression and associated soft-tissue abnormality (see Fig. 27.63). Plain X-rays may show bony destruction and soft-tissue abnormalities. Routine investigations, including chest X-ray, may provide evidence of systemic disease. If myelography is performed, CSF should be taken for analysis; in cases of complete spinal block, this shows a normal cell count with a very elevated protein causing yellow discoloration of the fluid (Froin syndrome). The risk of acute deterioration after myelography in spinal cord compression means that the neurosurgeons should be alerted before it is undertaken. Where a secondary tumour is causing the compression, needle biopsy may be required to establish a tissue diagnosis.

27.92 Symptoms of spinal cord compression

Pain

- Localised over the spine or in a root distribution, which may be aggravated by coughing, sneezing or straining

Sensory

- Paraesthesia, numbness or cold sensations, especially in the lower limbs, which spread proximally, often to a level on the trunk

Motor

- Weakness, heaviness or stiffness of the limbs, most commonly the legs

Sphincters

- Urgency or hesitancy of micturition, leading eventually to urinary retention

27.93 Signs of spinal cord compression

Cervical, above C5

- Upper motor neuron signs and sensory loss in all four limbs
- Diaphragm weakness (phrenic nerve)

Cervical, C5–T1

- Lower motor neuron signs and segmental sensory loss in the arms; upper motor neuron signs in the legs
- Respiratory (intercostal) muscle weakness

Thoracic cord

- Spastic paraplegia with a sensory level on the trunk
- Weakness of legs, sacral loss of sensation and extensor plantar responses

Cauda equina

- Spinal cord ends approximately at the T12/L1 spinal level and spinal lesions below this level can cause lower motor neuron signs only by affecting the cauda equina

27.94 Investigation of acute spinal cord syndrome

- Magnetic resonance imaging of spine or myelography
- Plain X-rays of spine
- Chest X-ray
- Cerebrospinal fluid
- Serum vitamin B_{12}

Management

Treatment and prognosis depend on the nature of the underlying lesion. Benign tumours should be surgically excised, and a good functional recovery can be expected unless a marked neurological deficit has developed before diagnosis. Extradural compression due to malignancy is the most common cause of spinal cord compression in developed countries and has a poor prognosis. Useful function can be regained if treatment, such as radiotherapy, is initiated within 24 hours of the onset of severe weakness or sphincter dysfunction; management should involve close cooperation with both oncologists and neurosurgeons (p. 169).

Spinal cord compression due to tuberculosis is common in some areas of the world and may require surgical treatment. This should be followed by appropriate antituberculous chemotherapy for an extended period. Traumatic lesions of the vertebral column require specialised neurosurgical treatment.

Intrinsic diseases of the spinal cord

There are many disorders that interfere with spinal cord function due to non-compressive involvement of the spinal cord itself. A list of these disorders is given in Box 27.95. The symptoms and signs are generally similar to those that would occur with extrinsic compression (see Boxes 27.92 and 27.93), although a suspended sensory loss (see Fig. 27.22F) can occur only with intrinsic disease such as syringomyelia. Urinary symptoms usually occur earlier in the course of an intrinsic cord disorder than with compressive disorders.

Investigation of intrinsic disease starts with imaging to exclude a compressive lesion. MRI provides most information about structural lesions, such as diastematomyelia, syringomyelia (Fig. 27.64) or intrinsic tumours. Non-specific signal change may be seen in the spinal cord in inflammatory (see Fig. 27.43) or infective conditions and metabolic disorders such as vitamin B_{12} deficiency. Lumbar puncture or blood tests may be required to make a specific diagnosis.

Diseases of peripheral nerves

Disorders of the peripheral nervous system are common and may affect the motor, sensory or autonomic components, either in isolation or in combination. The site of pathology may be nerve root (radiculopathy), nerve plexus (plexopathy) or nerve (neuropathy). Neuropathies may present as mononeuropathy (single nerve affected), multiple mononeuropathies ('mononeuritis multiplex') or a symmetrical polyneuropathy (Box 27.96). Cranial nerves 3–12 share the same tissue characteristics as peripheral nerves elsewhere and are subject to the same range of diseases.

Pathophysiology

Damage may occur to the nerve cell body (axon) or the myelin sheath (Schwann cell), leading to axonal or demyelinating neuropathies. The distinction is important, as only demyelinating neuropathies are usually susceptible to treatment. Making the distinction requires neurophysiology (nerve conduction studies and EMG). Neuropathies can occur in association with many systemic diseases, toxins and drugs (Box 27.97).

Clinical features

Motor nerve involvement produces features of a lower motor neuron lesion. Symptoms and signs of sensory nerve involvement depend on the type of sensory nerve involved; small-fibre neuropathies are often painful. Autonomic involvement may cause postural hypotension, disturbance of sweating, cardiac rhythm and gastrointestinal, bladder and sexual functions; isolated autonomic neuropathies are rare and more commonly complicate other neuropathies.

Investigations

The investigations required reflect the wide spectrum of causes (Box 27.98). Neurophysiological tests are key in discriminating

27.95 Intrinsic diseases of the spinal cord

Type of disorder	Condition	Clinical features
Congenital	Diastematomyelia (spina bifida)	Features variably present at birth and deteriorate thereafter LMN features, deformity and sensory loss of legs Impaired sphincter function Hairy patch or pit over low back Incidence reduced by increased maternal intake of folic acid during pregnancy
	Hereditary spastic paraplegia	Onset usually in adult life Autosomal dominant inheritance usual Slowly progressive UMN features affecting legs > arms Little or no sensory loss
Infective/ inflammatory	Transverse myelitis due to viruses (HZV), schistosomiasis, HIV, MS, sarcoidosis	Weakness and sensory loss, often with pain, developing over hours to days UMN features below lesion Impaired sphincter function
	Paraneoplastic	May predate tumour diagnosis
Vascular	Anterior spinal artery infarct due to atherosclerosis, aortic dissection, embolus	Abrupt onset Anterior horn cell loss (LMN) at level of lesion UMN features below it Spinothalamic sensory loss below lesion but dorsal column sensation spared
	Spinal AVM/dural fistula	Onset variable (acute to slowly progressive) Variable LMN, UMN, sensory and sphincter disturbance Symptoms and signs often not well localised to site of AVM
Neoplastic	Glioma, ependymoma	Weakness and sensory loss often with pain, developing over months to years UMN features below lesion in cord; additional LMN features in conus Impaired sphincter function
Metabolic	Vitamin B_{12} deficiency (subacute combined degeneration)	Progressive spastic paraparesis with proprioception loss Absent reflexes due to peripheral neuropathy
	Copper deficiency	± Optic nerve and cerebral involvement Excess dietary zinc
	Nitrous oxide toxicity	Modifies vitamin B_{12} metabolism
Degenerative	Motor neuron disease	Relentlessly progressive LMN and UMN features, associated bulbar weakness
	Syringomyelia	No sensory involvement Gradual onset over months or years, pain in cervical segments Anterior horn cell loss (LMN) at level of lesion, UMN features below it Suspended spinothalamic sensory loss at level of lesion, dorsal columns preserved (see Figs. 27.20 and 27.64)

(AVM = arteriovenous malformation; HIV = human immunodeficiency virus; HZV = herpes zoster virus; LMN = lower motor neuron; MS = multiple sclerosis; UMN = upper motor neuron)

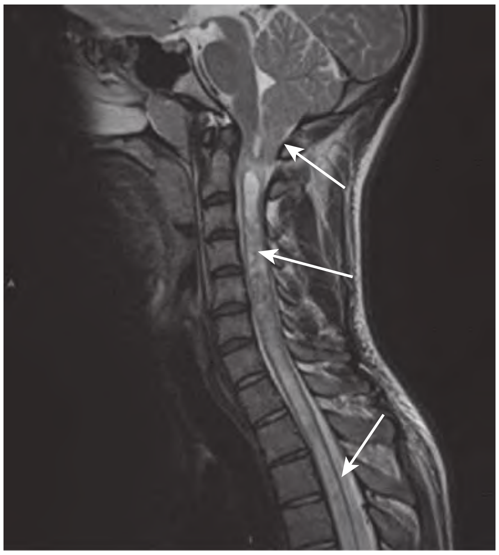

Fig. 27.64 Sagittal magnetic resonance image showing descent of cerebellar tonsils and central syrinx. The MRI shows descent of the cerebellar tonsils (top arrow), with a large central cord syrinx extending down from the cervical cord (middle arrow) to the thoracic cord (bottom arrow).

between demyelinating and axonal neuropathies, and in identifying entrapment neuropathies. Most neuropathies are of the chronic axonal type.

Entrapment neuropathy

Focal compression or entrapment is the usual cause of a mononeuropathy. Symptoms and signs of entrapment neuropathy are listed in Box 27.99. Entrapment neuropathies may affect anyone, but diabetes, excess alcohol or toxins, or genetic syndromes may be predisposing causes. Unless axonal loss has occurred, entrapment neuropathies will recover, provided the primary cause is removed, either by avoiding the precipitation of activity or by surgical decompression.

Multifocal neuropathy

Multifocal neuropathy (mononeuritis multiplex) is characterised by lesions of multiple nerve roots, peripheral nerves or cranial nerves (Box 27.100). Vasculitis is a common cause, either as part of a systemic disease or isolated to the nerves, or it may arise on a background of a polyneuropathy (e.g. diabetes). Multifocal motor neuropathy (MMN) with conduction block is a rare pure motor neuropathy, typically affecting the arms; it is associated with anti-GM1 antibodies in about 50% and responds to intravenous immunoglobulin.

27.96 Causes of polyneuropathy

Genetic

- Charcot–Marie–Tooth disease (CMT)
- Hereditary neuropathy with liability to pressure palsies (HNPP)
- Hereditary sensory ± autonomic neuropathies (HSN, HSAN)
- Familial amyloid polyneuropathy
- Hereditary neuralgic amyotrophy

Drugs

- Amiodarone
- Antibiotics (dapsone, isoniazid, metronidazole, ethambutol)
- Antiretrovirals
- Chemotherapy (cisplatin, vincristine, thalidomide)
- Phenytoin

Toxins

- Alcohol
- Nitrous oxide (recreational use)
- Rarely: lead, arsenic, mercury, organophosphates, solvents

Vitamin deficiencies

- Thiamin
- Pyridoxine
- Vitamin B_{12}
- Vitamin E

Infections

- Human immunodeficiency virus
- Leprosy
- Brucellosis

Inflammatory

- Guillain–Barré syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Vasculitis (polyarteritis nodosa, granulomatosis with polyangiitis (also known as Wegener granulomatosis), rheumatoid arthritis, systemic lupus erythematosus)
- Paraneoplastic (antibody-mediated)

Systemic medical conditions

- Diabetes
- Renal failure
- Sarcoidosis

Malignant disease

- Infiltration

Others

- Paraproteinaemias
- Amyloidosis
- Critical illness polyneuropathy/myopathy

27.97 Common causes of axonal and demyelinating chronic polyneuropathies

Axonal

- Diabetes mellitus
- Alcohol
- Uraemia
- Cirrhosis
- Amyloid
- Myxoedema
- Acromegaly
- Paraneoplasm
- Drugs and toxins (see Box 27.96)
- Deficiency states (see Box 27.96)
- Hereditary factors
- Infection (see Box 27.96)
- Idiopathic factors

Demyelinating

- Chronic inflammatory demyelinating polyradiculoneuropathy
- Multifocal motor neuropathy
- Paraprotein-associated demyelinating neuropathy
- Charcot–Marie–Tooth disease type I and type X

Polyneuropathy

A polyneuropathy is typically associated with a 'length-dependent' pattern, occurring in the longest peripheral nerves first and affecting the distal lower limbs before the upper limbs. Sensory symptoms and signs develop in an ascending 'glove and stocking' distribution. In inflammatory demyelinating neuropathies, the pathology may be more patchy, affecting the upper rather than lower limbs.

27.98 Investigation of peripheral neuropathy

Initial tests

- Glucose (fasting)
- Erythrocyte sedimentation rate, C-reactive protein
- Full blood count
- Urea and electrolytes
- Liver function tests
- Serum protein electrophoresis
- Vitamin B_{12}, folate
- ANA, ANCA, ENA
- Chest X-ray
- HIV testing

If initial tests are negative

- Nerve conduction studies
- Vitamins E and A
- Genetic testing (see Box 27.96)
- Lyme serology
- Serum angiotensin-converting enzyme
- Serum amyloid

(ANCA = antineutrophil cytoplasmic antibody; ANA = antineutrophil antibody; ENA = extractable nuclear antigen)

27.99 Symptoms and signs in common entrapment neuropathies

Nerve	Symptoms	Muscle weakness/ muscle wasting	Area of sensory loss
Median (at wrist) (carpal tunnel syndrome)	Pain and paraesthesia on palmar aspect of hands and fingers, waking patient from sleep. Pain may extend to arm and shoulder	Abductor pollicis brevis	Lateral palm and thumb, index, middle and lateral half fourth finger
Ulnar (at elbow)	Paraesthesia on medial border of hand, wasting and weakness of hand muscles	All small hand muscles, excluding abductor pollicis brevis	Medial palm and little finger, and medial half fourth finger
Radial	Weakness of extension of wrist and fingers, often precipitated by sleeping in abnormal posture, e.g. arm over back of chair	Wrist and finger extensors, supinator	Dorsum of thumb
Common peroneal	Foot drop, trauma to head of fibula	Dorsiflexion and eversion of foot	Nil or dorsum of foot
Lateral cutaneous nerve of the thigh (meralgia paraesthetica)	Tingling and dysaesthesia on lateral border of thigh	Nil	Lateral border of thigh

27.100 Causes of multifocal mononeuropathy

Axonal (defined on nerve conduction studies)

- Vasculitis (systemic or non-systemic)
- Diabetes mellitus
- Sarcoidosis
- Infection (HIV, hepatitis C, Lyme disease, leprosy, diphtheria)

Focal demyelination with/without conduction block

- Multifocal motor neuropathy
- Multiple compression neuropathies (usually in association with underlying disease, such as diabetes or alcoholism)
- Multifocal acquired demyelinating sensory and motor neuropathy (MADSAM)
- Hereditary neuropathy with a predisposition to pressure palsy (autosomal dominant, peripheral myelin protein 22 gene)
- Lymphoma

Guillain–Barré syndrome

Guillain–Barré syndrome (GBS) is a heterogeneous group of immune-mediated conditions of acute peripheral nerve inflammation, with an incidence of 1–2/100 000/year. In Europe and North America, the most common variant is an acute inflammatory demyelinating polyneuropathy (AIDP). Axonal variants, either motor (acute motor axonal neuropathy, AMAN) or sensorimotor, are more common in China and Japan, and account for 10% of GBS in Western countries, often associated with *Campylobacter jejuni*. The hallmark is an acute paralysis evolving over days or weeks, with loss of tendon reflexes. About two-thirds of those with AIDP have a prior history of infection, and an autoimmune response triggered by the preceding infection is thought to cause peripheral nerve inflammation. A number of GBS variants have been described, associated with specific anti-ganglioside antibodies; the best recognised is Miller Fisher syndrome, which involves anti-GQ1b antibodies.

Clinical features

Distal paraesthesia and pain precede muscle weakness that ascends rapidly from lower to upper limbs and is more marked proximally than distally. Facial and bulbar weakness commonly develops, and respiratory weakness requiring ventilatory support occurs in 20% of cases. Weakness progresses over a maximum of 4 weeks (usually less). Rapid deterioration to respiratory failure can develop within hours. Examination shows diffuse weakness with loss of reflexes. Miller Fisher syndrome presents with internal and external ophthalmoplegia, ataxia and areflexia.

Investigations

The CSF protein is raised, but may be normal in the first 10 days. There is usually no increase in CSF white cell count (> 50×10^6 cells/L suggests an alternative diagnosis; though the cell count may be considerably higher in HIV infection). Electrophysiological changes may emerge after a week or so, with conduction block and multifocal motor slowing, sometimes most evident proximally as delayed F waves. Antibodies to the ganglioside GM1 are found in about 25%, usually the motor axonal form. Other causes of an acute neuromuscular paralysis should be considered (e.g. poliomyelitis, botulism, acute intermittent porphyria, diphtheria, spinal cord syndromes or myasthenia), via the history and examination. Nerve roots are an important site of inflammation, and contrast uptake is sometimes seen here in contrast-enhanced MRI spinal cord imaging.

Management

Active treatment with plasma exchange or intravenous immunoglobulin therapy shortens the duration of ventilation and improves prognosis. In severe GBS, both intravenous immunoglobulin (IVIg) and plasma exchange started within 2 weeks of onset hasten recovery, with similar rates of adverse effects but IVIg treatment is significantly more likely to be completed than plasma exchange. The choice of treatment often depends on logistical considerations. Overall, 80% of patients recover completely within 3–6 months, 4% die and the remainder suffer residual neurological disability, which can be severe. Regular monitoring of respiratory function (vital capacity) is needed in the acute phase, as respiratory failure may develop with little warning. Adverse prognostic features include older age, rapid deterioration to ventilation and evidence of axonal loss on EMG. Supportive measures to prevent pressure sores and deep venous thrombosis are essential.

Chronic polyneuropathy

The most common axonal and demyelinating causes of polyneuropathy are shown in Box 27.97. A chronic symmetrical axonal polyneuropathy, evolving over months or years, is the most common form of chronic neuropathy. Diabetes mellitus is the most common cause but in about 25%–50% no cause can be found.

Hereditary neuropathy

Charcot–Marie–Tooth disease (CMT) is an umbrella term for the inherited neuropathies. The members of this group of syndromes have different clinical and genetic features. The most common CMT is the autosomal dominantly inherited CMT type 1, usually caused by a duplication in the *PMP-22* gene. Common signs are distal wasting ('inverted champagne bottle' legs), often with pes cavus, and predominantly motor involvement. X-linked and recessively inherited forms of CMT, causing demyelinating or axonal neuropathies, also occur.

Chronic demyelinating polyneuropathy

The acquired chronic demyelinating neuropathies include chronic inflammatory demyelinating peripheral neuropathy (CIDP), multifocal motor neuropathy (see above) and paraprotein-associated demyelinating neuropathy. CIDP typically presents with relapsing or progressive motor and sensory changes, evolving over more than 8 weeks (in distinction to the more acute GBS). It is important to recognise, as it usually responds to intravenous immunoglobulin and other immunotherapies such as glucocorticoids or plasma exchange.

Some 10% of patients with acquired demyelinating polyneuropathy have an abnormal serum paraprotein, sometimes associated with a monoclonal gammopathy of uncertain significance (MGUS) or lymphoproliferative malignancy. Those with distal sensory involvement and prominent neuropathic tremor may also demonstrate positive antibodies to myelin-associated glycoprotein (MAG antibodies).

Brachial plexopathy

Trauma usually damages either the upper or the lower parts of the brachial plexus, according to the mechanics of the injury. The clinical features depend on the anatomical site of the damage (Box 27.101). Lower parts of the brachial plexus are vulnerable to infiltration from breast or apical lung tumours (Pancoast tumour) or damage by therapeutic irradiation. The lower plexus may also be compressed by a cervical rib or fibrous band between C7 and the first rib at the thoracic outlet.

Neuralgic amyotrophy (also known as brachial neuritis) presents as an acute brachial plexopathy of probable inflammatory origin. Severe shoulder pain precedes the appearance of a patchy upper brachial plexus lesion, with motor and/or sensory involvement. There is no specific treatment and recovery is often incomplete; it may recur in about 25% and there is a rare autosomal dominant hereditary form. The appearance of vesicles should indicate the alternative diagnosis of motor zoster.

Lumbosacral plexopathy

Lumbosacral plexus lesions may be caused by neoplastic infiltration or compression by retroperitoneal haematomas. A small-vessel vasculopathy can produce a unilateral or bilateral lumbar plexopathy in association with diabetes mellitus ('diabetic amyotrophy') or an idiopathic form in non-diabetic patients. This presents with painful wasting of the quadriceps with weakness of knee extension and an absent knee reflex.

27.101 Physical signs in brachial plexus lesions

Site	Affected muscles	Sensory loss
Upper plexus	Biceps, deltoid, spinati, rhomboids, brachioradialis (triceps, serratus anterior)	Patch over deltoid
Lower plexus	All small hand muscles, claw hand (ulnar wrist flexors)	Ulnar border of hand/ forearm
Thoracic outlet syndrome	Small hand muscles, ulnar forearm	Ulnar border of hand/ forearm/upper arm

Spinal root lesions

Spinal root lesions (radiculopathy) are described above. Clinical features include muscle weakness and wasting and dermatomal sensory and reflex loss, which reflect the pattern of the roots involved. Pain in the muscles innervated by the affected roots may be prominent.

Diseases of the neuromuscular junction

Myasthenia gravis

This is the most common cause of acutely evolving, fatigable weakness and preferentially affects ocular, facial and bulbar muscles.

Pathophysiology

Myasthenia gravis is an autoimmune disease, most commonly (80% of cases) caused by antibodies to acetylcholine receptors in the post-junctional membrane of the neuromuscular junction. The resultant blockage of neuromuscular transmission and complement-mediated inflammatory response reduces the number of acetylcholine receptors and damages the end plate (Fig. 27.65). Other antibodies can produce a similar clinical picture, most notably autoantibodies to muscle-specific kinase (MuSK), which is involved in the regulation and maintenance of acetylcholine receptors.

About 15% of patients (mainly those with late onset) have a thymoma, most of the remainder displaying thymic follicular hyperplasia. Myasthenic patients are more likely to have associated organ-specific autoimmune diseases. Triggers are not always evident but some drugs (e.g. penicillamine) can precipitate an antibody-mediated myasthenic syndrome that may persist after drug withdrawal. Other drugs, especially aminoglycosides and quinolones, may exacerbate the neuromuscular blockade and should be avoided in patients with myasthenia.

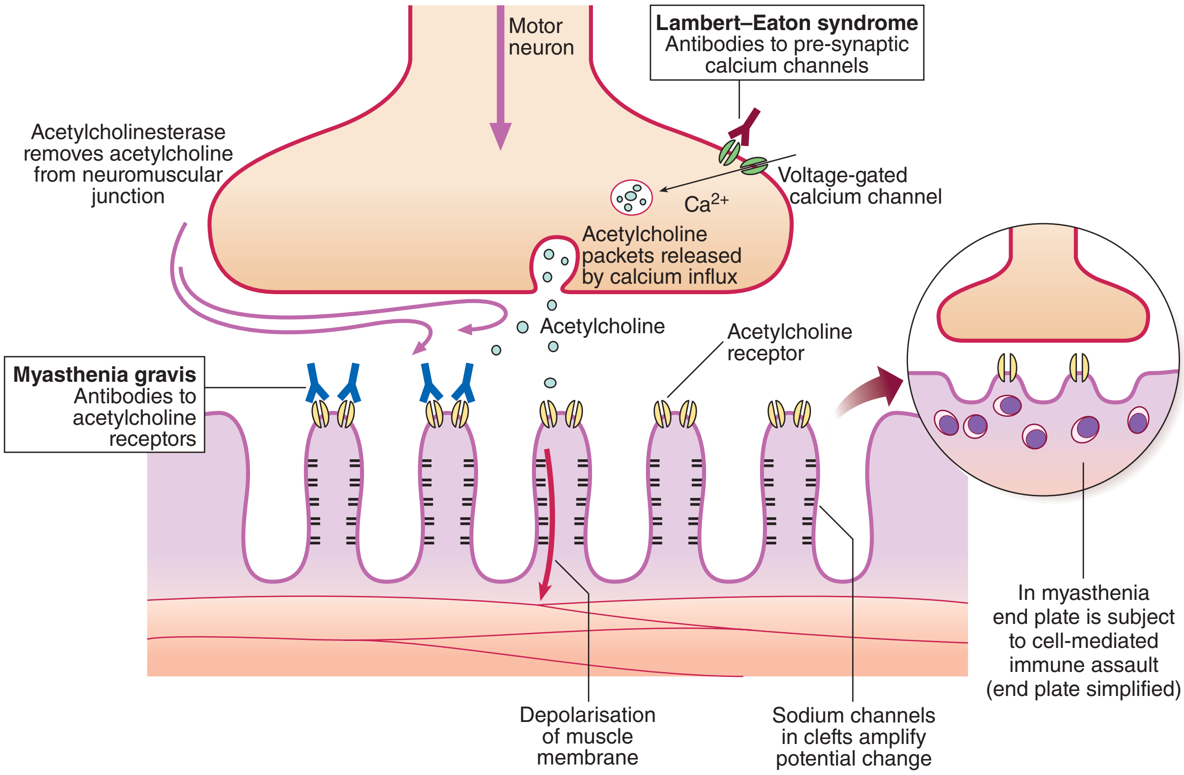
Clinical features

Myasthenia gravis usually presents between the ages of 15 and 50 years and there is a female preponderance in younger patients. In older patients, males are more commonly affected. It tends to run a relapsing and remitting course.

The most evident symptom is fatigable muscle weakness; movement is initially strong but rapidly weakens as muscle use continues. Worsening of symptoms towards the end of the day or following exercise is characteristic. There are no sensory signs or signs of involvement of the CNS, although weakness of the oculomotor muscles may mimic a central eye movement disorder. The first symptoms are usually intermittent ptosis or diplopia but weakness of chewing, swallowing, speaking or limb movement also occurs. Resting of the eyelids (looking downwards) may be followed by increased reflex elevation with up-gaze (so-called Cogan lid twitch sign). Any limb muscle may be affected, most commonly those of the shoulder girdle; the patient is unable to undertake tasks above shoulder level, such as combing the hair, without frequent rests. Respiratory muscles may be involved and respiratory failure is an avoidable cause of death. Aspiration may occur if the cough is ineffectual. Ventilatory support is required where weakness is severe or of abrupt onset. Subtypes of myasthenia gravis include ocular myasthenia, where disease is often confined to eye muscles, and generalised myasthenia, where more widespread muscle involvement is seen which can include bulbar and respiratory muscles. There is often overlap between these subtypes. Congenital (genetic) forms of myasthenia also exist and do not have an autoimmune basis.

Investigations

Serological investigations play an important role in the diagnosis of myasthenia gravis. Acetylcholine receptor antibodies are highly specific, but seronegative cases also exist and further serological testing, e.g. for MuSK antibodies, should be performed if AChR antibodies are negative. Anti-MuSK antibodies are associated with prominent bulbar involvement.



Motor neuron
Lambert–Eaton syndrome Antibodies to pre-synaptic calcium channels
Acetylcholinesterase removes acetylcholine from neuromuscular junction
Voltage-gated calcium channel
Ca^{2+}
Acetylcholine packets released by calcium influx
Acetylcholine
Acetylcholine receptor
Myasthenia gravis Antibodies to acetylcholine receptors
In myasthenia end plate is subject to cell-mediated immune assault (end plate simplified)
Depolarisation of muscle membrane
Sodium channels in clefts amplify potential change

Fig. 27.65 **Myasthenia gravis and Lambert–Eaton myasthenic syndrome (LEMS).** In myasthenia there are antibodies to the acetylcholine receptors on the post-synaptic membrane, which block conduction across the neuromuscular junction (NMJ). Myasthenic symptoms can be transiently improved by inhibition of acetylcholinesterase (e.g. with Tensilon – edrophonium bromide), which normally removes the acetylcholine. A cell-mediated immune response produces simplification of the post-synaptic membrane, further impairing the 'safety factor' of neuromuscular conduction. In LEMS, antibodies to the pre-synaptic voltage calcium channels impair release of acetylcholine from the motor nerve ending; calcium is required for the acetylcholine-containing vesicle to fuse with the pre-synaptic membrane for release into the NMJ.

Neurophysiological assessment is important in establishing the diagnosis. Repetitive stimulation during nerve conduction studies may show a characteristic decremental response if the muscle has been clinically affected. Specialised single fibre EMG changes such as ‘jitter’ may also be seen. All patients should have a thoracic CT or MRI to exclude thymoma, especially those without anti-acetylcholine receptor antibodies. Screening for associated autoimmune disorders, particularly thyroid disease, is important.

Intravenous injection of the short-acting anticholinesterase edrophonium bromide (the Tensilon test) is less widely used than before and requires specialist involvement in cases where there is diagnostic doubt. Structural imaging (e.g. MRI of brainstem) may be needed to exclude alternative diagnoses that can cause ocular–bulbar weakness.

Management

The goals of treatment are to maximise the activity of acetylcholine at remaining receptors in the neuromuscular junctions and to limit or abolish the immunological attack on motor end plates.

The duration of action of acetylcholine is prolonged by inhibiting acetylcholinesterase. The most commonly used anticholinesterase drug is pyridostigmine. Muscarinic side-effects, including diarrhoea and colic, may be controlled by propantheline.

Myasthenia gravis can cause life-threatening disease, often referred to as ‘myasthenic crisis’, when bulbar and respiratory failure occurs. Prompt acute immunotherapy, often using intravenous immunoglobulin or plasma exchange, is required, together with a longer-term immunosuppressive approach. Supportive respiratory care, and early involvement of intensive care teams, is important during these periods.

Immunological treatment of myasthenia is outlined in Box 27.102. Thymoma should be managed with joint oncology and thoracic surgery input. Prognosis is variable and remissions may occur spontaneously. When myasthenia is entirely ocular, prognosis is excellent and disability slight. Younger seropositive patients with generalised disease may benefit from thymectomy in the absence of thymoma, while older patients are less likely to have a remission despite treatment. Rapid progression of the disease more than 5 years after onset is uncommon.

Some medications, such as aminoglycoside antibiotics, can worsen myasthenia gravis (myaware.org provides a list of drugs to avoid).

27.102 Immunological treatment of myasthenia

Acute treatments

Intravenous immunoglobulin

- Lowers production of antibodies and rapidly reduces weakness

Plasma exchange

- Removing antibody from the blood may produce marked improvement; this is usually brief, so is normally reserved for myasthenic crisis or for pre-operative preparation

Long-term treatments

Glucocorticoid treatment

- Improvement can be preceded by marked exacerbation of myasthenic symptoms, so treatment should be initiated cautiously in an environment where deterioration can be managed. In an outpatient setting many neurologists start corticosteroids at a low dose and increase gradually. If urgent high-dose steroids are needed this may require hospital admission
- Usually necessary to continue for months or years, risking adverse effects

Pharmacological immunosuppression treatment

- Azathioprine 2.5 mg/kg daily reduces the necessary dosage of glucocorticoids and may allow withdrawal. Effect on clinical features may be delayed for months
- Mycophenolate mofetil lacking
- Antibody based biologic therapies, e.g. Efgartigimod alfa

Thymectomy

- Likely to be required for thymoma
- Should be considered in any antibody-positive patient under 45 years with symptoms not confined to extraocular muscles, unless the disease has been established for more than 7 years

Lambert–Eaton myasthenic syndrome

Other rarer conditions can present with muscle weakness due to impaired transmission across the neuromuscular junction. The most common of these is the Lambert–Eaton myasthenic syndrome (LEMS), which can occur as an inflammatory or paraneoplastic phenomenon. Antibodies to pre-synaptic voltage-gated calcium channels (see Fig. 27.65) impair transmitter release. Patients may have autonomic dysfunction (e.g. dry mouth) in addition to muscle weakness but the cardinal clinical sign is absence of tendon reflexes, which return after sustained contraction of the relevant muscle. The condition is associated with underlying malignancy in a high percentage of cases and investigation must be directed towards identifying any neoplasm. Diagnosis is made electrophysiologically on the presence of post-tetanic potentiation of motor response to nerve stimulation at a frequency of 20–50/sec. Treatment is with 3,4-diaminopyridine, or pyridostigmine and immunosuppression.

Diseases of muscle

Muscle disease, either hereditary or acquired, is rare. Most typically, it presents with a proximal symmetrical weakness. Diagnosis is dependent on recognition of clinical clues, such as cardiorespiratory involvement, evolution, family history, exposure to drugs, the presence of contractures, myotonia and other systemic features, and on investigation findings, most importantly EMG and muscle biopsy. Hereditary syndromes include the muscular dystrophies, muscle channelopathies, metabolic myopathies (including mitochondrial diseases) and congenital myopathies.

Muscular dystrophies

These are inherited disorders with progressive muscle destruction and may be associated with cardiac and/or respiratory involvement and sometimes non-myopathic features (Box 27.103). Myotonic dystrophy is the most common, with a prevalence of about 12/100 000.

Clinical features

The pattern of the clinical features is defined by the specific syndromes. Onset is often in childhood, although some patients, especially those with myotonic dystrophy, may present as adults. Wasting and weakness are usually symmetrical, without fasciculation or sensory loss, and tendon reflexes are usually preserved until a late stage. Weakness is usually proximal, except in myotonic dystrophy type 1, when it is distal.

Investigations

The diagnosis can be confirmed by specific molecular genetic testing, supplemented with EMG and muscle biopsy if necessary. Creatine kinase is markedly elevated in the dystrophinopathies (Duchenne and Becker) but is normal or moderately elevated in the other dystrophies. Screening for an associated cardiac abnormality (cardiomyopathy or dysrhythmia) is important.

Management

There is no specific therapy for most of these conditions but physiotherapy and occupational therapy help patients cope with their disability. Glucocorticoids can be used in Duchenne muscular dystrophy but side-effects should be anticipated and avoided by dose modification. Treatment of associated cardiac failure or arrhythmia (with pacemaker insertion if necessary) may be required; similarly, management of respiratory complications (including nocturnal hypoventilation) can improve quality of life. Improvements in non-invasive ventilation have led to significant improvements in survival for patients with Duchenne muscular dystrophy. Genetic counselling is important.

27.103 The muscular dystrophies

Type	Genetics	Age of onset	Muscles affected	Other features
Myotonic dystrophy (DM1)	Autosomal dominant; expanded triplet repeat *DMPK* gene	Any	Face (including ptosis), sternomastoids, distal limb, generalised later	Myotonia, cognitive impairment, cardiac conduction abnormalities, lens opacities, frontal balding, hypogonadism
Proximal myotonic myopathy (PROMM; DM2)	Autosomal dominant; quadruplet repeat expansion in *CNBP* gene	8–50 years	Proximal, especially thigh, sometimes muscle hypertrophy	As for DM1 but cognition not affected Muscle pain
Duchenne	X-linked; deletions in *dystrophin* gene Xp21	< 5 years	Proximal and limb girdle	Cardiomyopathy and respiratory failure
Becker	X-linked; deletions in *dystrophin* gene Xp21	Childhood/early adulthood	Proximal and limb girdle	Cardiomyopathy common but respiratory failure uncommon
Limb girdle	Many pathogenic variants on different chromosomes	Childhood/early adulthood	Limb girdle	Very variable depending on genetic subtype, some involve cardiac and respiratory systems
Facioscapulohumeral (FSH)	Autosomal dominant; tandem repeat deletion chromosome 4q35	7–30 years	Face and upper limb girdle, distal lower limb weakness	Pain in shoulder girdle common, deafness Cardiorespiratory involvement rare
Oculopharyngeal	Autosomal dominant and recessive; triplet repeat expansion in *PABP2* gene chromosome 14q	30–60 years	Ptosis, external ophthalmoplegia, dysphagia, tongue weakness	Mild lower limb weakness
Emery–Dreifuss	X-linked recessive; pathogenic variants in *emerin* gene	4–5 years	Humero-peroneal, proximal limb girdle later	Contractures develop early Cardiac involvement leads to sudden death

27.104 Inherited disorders of muscle metabolism

Disease	Clinical features	Diagnosis
Carbohydrate (glycogen) metabolism		
Myophosphorylase deficiency (McArdle disease): autosomal recessive	Exercise-induced myalgia, stiffness, weakness (with 'second wind' phenomenon), myoglobinuria	Creatine kinase (CK) elevated Muscle biopsy Enzyme assay
Acid maltase deficiency (Pompe disease): autosomal recessive	Infantile form: death within 2 years	CK elevated
	Childhood: death in twenties or thirties	Blood lymphocyte analysis for glycogen granules
	Adult: progressive proximal myopathy with respiratory failure	Muscle biopsy Enzyme assay
Lipid metabolism (β-oxidation)		
Carnitine-palmitoyl transferase (CPT) deficiency	Myalgia *after* exercise, myoglobinuria, weakness	CK normal between attacks Urinary organic acids Enzyme assays Muscle biopsy

27.105 Mitochondrial syndromes

Syndrome	Clinical features
Myoclonic epilepsy with ragged red fibres (MERRF)	Myoclonic epilepsy, cerebellar ataxia, dementia, sensorineural deafness ± peripheral neuropathy, optic atrophy and multiple lipomas
Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)	Episodic encephalopathy, stroke-like episodes often preceded by migraine-like headache, nausea and vomiting
Chronic progressive external ophthalmoplegia (CPEO)	Progressive ptosis and external oculomotor palsy, proximal myopathy ± deafness, ataxia and cardiac conduction defects
Kearns–Sayre syndrome	Like CPEO but early age of onset (< 20 years), heart block, pigmentary retinopathy
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)	Progressive ptosis, external oculomotor palsy, gastrointestinal dysmotility (often pseudo-obstruction), diffuse leucoencephalopathy, thin body habitus, peripheral neuropathy and myopathy
Neuropathy, ataxia and retinitis pigmentosa (NARP)	Weakness, ataxia and progressive loss of vision, along with dementia, seizures and proximal weakness

Inherited metabolic myopathies

There are a large number of rare inherited disorders that interfere with the biochemical pathways that maintain the energy supply (adenosine triphosphate, ATP) to muscles. These are mostly recessively inherited deficiencies in the enzymes necessary for glycogen or fatty acid (β-oxidation) metabolism (Box 27.104). They typically present with muscle weakness and pain.

Mitochondrial disorders

Mitochondrial diseases are discussed on page 47. Mitochondria are present in all tissues and dysfunction causes widespread effects on vision (optic atrophy, retinitis pigmentosa, cataracts), hearing (sensorineural deafness) and the endocrine, cardiovascular, gastrointestinal and renal systems. Any combination of these should raise the suspicion of a mitochondrial disorder, especially if there is evidence of maternal transmission.

Mitochondrial dysfunction can be caused by alterations in either mitochondrial DNA or genes encoding for oxidative processes. Genetic abnormalities or pathogenic variants in mitochondrial DNA may affect single individuals and single tissues (most commonly muscle). Thus, patients with exercise intolerance, myalgia and sometimes recurrent myoglobinuria may have isolated pathogenic variants in genes encoding for oxidation pathways.

Inherited disorders of the oxidative pathways of the respiratory chain in mitochondria cause a group of disorders, either restricted to the muscle or associated with non-myopathic features (Box 27.105). Many of these mitochondrial disorders are inherited via the mitochondrial genome, down the maternal line. Diagnosis is based on clinical appearances, supported by muscle biopsy appearance (usually with 'ragged red' and/or cytochrome oxidase-negative fibres), and specific pathogenic variants either on blood or, more reliably, muscle testing. Pathogenic variants may be due either to point pathogenic variants or to deletions of mitochondrial DNA.

A disorder called Leber hereditary optic neuropathy (LHON) is characterised by acute or subacute loss of vision, most frequently in males, due to bilateral optic atrophy. Three point pathogenic variants account for more than 90% of LHON cases.

Channelopathies

Inherited abnormalities of the sodium, calcium and chloride ion channels in striated muscle produce various syndromes of familial periodic paralysis, myotonia and malignant hyperthermia, which may be recognised by their clinical characteristics and potassium abnormalities (Box 27.106). Genetic testing is available.

Acquired myopathies

These include the inflammatory myopathies, or myopathy associated with a range of metabolic and endocrine disorders or drug and toxin exposure (Fig. 27.66).

27.106 Muscle channelopathies

Channel	Muscle disease	Gene and inheritance	Clinical features
Sodium	Paramyotonia congenita	*SCN4A* (17q35) Autosomal dominant	Cold-evoked myotonia with episodic weakness provoked by exercise and cold
	Potassium-aggravated myotonia	*SCN4A*	Pure myotonia without weakness provoked by potassium
	Hyperkalaemic periodic paralysis	*SCN4A* Autosomal dominant	Brief (mins to hours), frequent episodes of weakness provoked by rest, cold, potassium, fasting, pregnancy, stress Less common than hypokalaemic periodic paralysis
	Hypokalaemic periodic paralysis	*SCN4A* Autosomal dominant (one-third new pathogenic variants)	Longer (hours to days) episodic weakness triggered by rest, carbohydrate loading, cold
Chloride	Myotonia congenita:		
	Thomsen disease	*CLCN1* Autosomal dominant	Myotonia usually mild, little weakness
	Becker disease	*CLCN1* Autosomal recessive	Myotonia often severe, transient weakness
Calcium	Hypokalaemic periodic paralysis	*CACNA1S* Autosomal dominant	Episodic weakness triggered by carbohydrate meal
	Malignant hyperthermia	*CACNA1S*, *CACNL2A* Autosomal dominant	Hyperpyrexia due to excess muscle activity, precipitated by drugs, usually anaesthetic agents; most common cause of death during general anaesthetic
Potassium	Hypokalaemic periodic paralysis with cardiac arrhythmia	*KCNJ2* Autosomal dominant	Similar to hypokalaemic periodic paralysis, associated with cardiac and non-myopathic features (skeletal and facial)
Ryanodine receptor	Malignant hyperthermia	*RYR1* (19q13)*RYR1*	As malignant hyperthermia above
	Central core and multicore disease	Mostly autosomal dominant	Present in infancy with mild progressive weakness

Multiple Choice Questions

27.1. A patient describes a two-day history of progressive tingling and numbness, starting in both feet but now including both arms. She has difficulty walking today. Examination shows mildly reduced sensation in arms and legs and mild weakness, with reduced reflexes. Where is the most likely location of the lesion?

A. Cerebral hemispheres
B. Spinal cord
C. Nerve roots and peripheral nerve
D. Neuromuscular junction
E. Muscle

Answer: C.

The symmetrical involvement of both sensory and motor modalities, together with reduced reflexes, is consistent with a peripheral nerve localisation. Evolution of symptoms over this time course suggests an inflammatory cause, such as Guillain–Barré syndrome (GBS). Prompt recognition is important since bulbar and respiratory weakness can develop, and supportive care, including respiratory support, can be required. GBS responds to treatment with intravenous immunoglobulin or plasma exchange. Neuromuscular disease and muscle disease do not cause sensory disturbance, and lesions in the spinal cord or cerebral hemispheres are usually associated with brisk reflexes.

27.2. Which of the following statements about neuroimaging is true?

A. Computed tomography should always be performed before lumbar puncture in suspected meningitis
B. Computed tomography is the investigation of choice for a thunderclap headache
C. Accurate imaging of cerebral blood vessels requires invasive angiography
D. A diagnosis of multiple sclerosis (MS) always requires magnetic resonance (MR) imaging
E. Parkinson disease should only be diagnosed following a positive dopamine active transporter (DAT) scan

Answer: B.

Thunderclap headache (a very severe headache of abrupt onset, reaching maximum intensity within 60 seconds) should always raise the possibility of a serious underlying cause and is a medical emergency. An important cause is subarachnoid haemorrhage. Computed tomography is a rapid and widely available imaging modality for detection of acute bleeding. Modern neuroimaging allows blood vessels to be visualised without the need for invasive angiography. MR imaging plays an important role in the diagnosis of MS by helping to demonstrate dissemination of lesions in time and space, and excluding alterative diagnoses; however, MS can also be diagnosed in settings where MR imaging is not available.

27.3. A 65-year-old man from the UK presents with a three-day history of bilateral leg weakness and numbness. Last year he had an episode of left optic neuritis, which did not fully resolve. On examination he is afebrile, with severe bilateral leg weakness (MRC power grade 1/5 throughout) and has brisk lower limb reflexes with a sensory level at T4. Magnetic resonance imaging (MRI) shows an inflammatory lesion in the thoracic spinal cord stretching from T3 to T7. What is the most specific diagnostic investigation to be performed next?

A. Cerebrospinal fluid (CSF) analysis for oligoclonal bands
B. CSF analysis for schistosomiasis
C. Blood test for aquaporin-4 antibodies
D. MRI of the head
E. Whole-body positron emission tomography (PET)

Answer: C.

The clinical syndrome is severe optic nerve and spinal cord inflammation, with imaging evidence of longitudinally extensive transverse myelitis (LETM). While optico-spinal inflammation is most commonly seen in multiple sclerosis (MS), the severe nature of both lesions and the long spinal cord lesion (over 3 vertebral segments in length) are not typical for MS. While infections, including schistosomiasis, can cause long spinal cord lesions, the most likely cause for this clinical picture is neuromyelitis optica spectrum disorder (NMOSD), and aquaporin-4 antibodies are highly specific for this diagnosis. NMOSD can also occur with myelin oligodendrocyte glycoprotein (MOG) antibodies, as well as seronegative cases.

27.4. Which of the following statements about cryptococcal meningitis is true?

A. Only immunosuppressed individuals develop cryptococcal meningitis
B. Cryptococcal meningitis is a cause of high cerebrospinal fluid protein and glucose
C. Cerebrospinal fluid India ink test is the investigation of choice for cryptococcal meningitis
D. High cerebrospinal fluid pressure in cryptococcal meningitis is treated with frequent, often daily, lumbar punctures
E. Cryptococcal antigen may be present in cerebrospinal fluid, but not in the serum

Answer: D.

Although cryptococcal meningitis (CM) usually occurs in the immunosuppressed, it can occur in the immunocompetent. CM results in a high cerebrospinal fluid (CSF) protein and low CSF glucose. Cryptococcal antigen is present in the CSF and sometimes the serum. The India ink test is still used in some regions but sensitivity is limited, particularly in non-HIV-related CM. High CSF pressure in CM is treated with frequent, sometimes daily, lumbar punctures.

27.5. Which of the following statements about seizures is true?

A. All patients who have had a confirmed seizure should be told not to drive
B. The electroencephalogram (EEG) is always abnormal in people with epilepsy
C. Neuroimaging should be performed on all individuals who have had a generalised seizure
D. Neuroimaging is not required for individuals who have had a focal seizure
E. Anticonvulsants should be started after a first seizure

Answer: A.

It is the physician's prime duty to ensure that the patient is aware of the legal obligation to stop driving and inform the relevant driving authority after having a single seizure. In the UK, patients are usually eligible to drive a motor vehicle six months after a single seizure provided there are no factors that would increase the risk of further seizure. There are far more stringent criteria for heavy goods and public service vehicle drivers. EEG can be normal in people with epilepsy, and neuroimaging is particularly important in individuals who have focal-onset seizures.

27.6. A 75-year-old woman presents with a transient episode of right facial weakness, right hand weakness and dysarthria, witnessed by her daughter. At her clinic appointment she has a blood pressure of 175/95 mmHg. Which area of the brain is likely to have been involved in her symptoms?

A. Right parietal lobe
B. Left occipital lobe
C. Brainstem
D. Left frontal lobe
E. All of the above

Answer: D.

The right face and hand weakness makes involvement of the contralateral motor cortex, in the precentral gyrus of frontal lobe, most likely.

27.7. In the same patient, stenosis of a cervical artery is found on a CT angiogram of her neck vessels. Which stenosis or stenoses would be an indication for surgical intervention?

A. Left internal carotid stenosis
B. Right carotid stenosis
C. Left vertebral artery stenosis
D. Left subclavian stenosis
E. Left external carotid stenosis

Answer: A.

Left internal carotid stenosis: stenoses of the other arteries indicate large vessel atheroma, but none would be expected to lead to a left hemisphere transient ischaemic attack.

27.8. For the same patient, a left carotid endarterectomy is planned. Which of the following treatments should be considered (choose all that apply)?

A. Carotid endarterectomy only
B. Blood pressure lowering
C. LDL cholesterol lowering
D. Antiplatelet agent
E. Anticoagulant

Answer: B, C, D.

Blood pressure lowering, LDL cholesterol lowering and an antiplatelet are all indicated here in addition to carotid endarterectomy. An anticoagulant is only indicated if atrial fibrillation is identified.

27.9. A 54-year-old man has a sudden onset of a severe left hemiparesis and left facial weakness. He has no pain. He is inattentive to his left side. He has atrial fibrillation. He arrives at the emergency department 1 hour after the onset of the symptoms. Which are the best differential diagnoses (choose all that apply)?

A. Ischaemic stroke
B. Intracerebral haemorrhage
C. Subarachnoid haemorrhage
D. Transient ischaemic attack
E. Brain tumour

Answer: A, B.

This man has presented with an acute focal neurological deficit that is severe at 3 hours. This is unlikely to be due to a TIA, and a subarachnoid haemorrhage usually presents with headache or, when severe, coma. Rarely a bleed from a ruptured aneurysm can be predominantly parenchymal with little subarachnoid blood. The sudden onset of symptoms makes a brain tumour unlikely. Both an intracerebral haemorrhage and an ischaemic stroke present with a stroke syndrome.

27.10. In the same patient, a CT of the brain is performed within 30 minutes of his arrival to the emergency department, and this CT head is normal at first review. Which of the following statements best describes the situation?

A. An ischaemic stroke is the likeliest diagnosis and thrombolysis is appropriate
B. An ischaemic stroke is the likeliest diagnosis and thrombolysis is not appropriate
C. Multiple sclerosis is the likeliest diagnosis and steroids are most appropriate
D. Immediate thrombectomy is the next best step
E. Intravenous heparin is appropriate

Answer: A.

A normal CT scan does not preclude a diagnosis of ischaemic stroke, which is the most likely diagnosis here. Because this is the case, thrombolysis is the most important action; thrombectomy is also likely to be indicated, but would need the identification of an occluded artery with an angiogram. A sudden onset of severe cortical symptoms is not a common presentation of multiple sclerosis. Intravenous heparins do not improve recovery in acute ischaemic stroke, even with atrial fibrillation.

- Rebound tonometry, e.g. iCare device (**B**)

4 Pupil assessment
- Anisocoria
- Direct/consensual response
- Relative afferent pupillary defect (RAPD)
- Near accommodation (light-near dissociation)

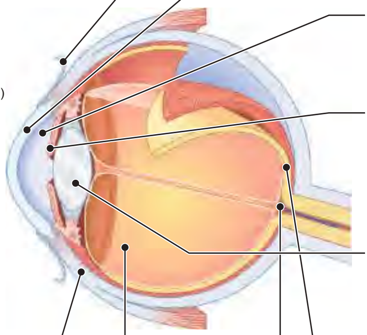
5 Colour vision
- Red desaturation
- Ishihara test plates (**C**)

6 Ocular motility
- Cover test – (eso-/exotropia)
- Alternating cover test (eso-/exophoria)
- Stereopsis assessment (Frisby/Lang/TNO stereo tests)

7 Visual field assessment
- Confrontation
- Automated perimetry (24–2 Humphrey visual field – bitemporal hemianopia) (**D**)

8 Eyelids
- Ptosis/lagophthalmos
- Ectropion (**E**)/entropion
- Lid lesions
- Blepharitis

9 Sclera
- Blue sclera (osteogenesis imperfecta/Ehlers–Danlos syndrome)
- Episcleritis
- Scleritis
- Thinning (scleromalacia)
- Icterus (secondary to jaundice)
- Nodules



10 Conjunctiva
- Hyperaemia
- Chemosis
- Discharge
- Papillae / follicles
- Pigmentation
- Symblepharon

11 Cornea
- Foreign bodies
- Corneal laceration / abrasion
- Epithelial defects
- Punctate erosions
- Keratitis (viral / bacterial / fungal)
- Keratitic precipitates (**F**)
- Corneal oedema

12 Anterior chamber
- Cells/flare/fibrin
- Hypopyon (**G**)
- Hyphaema (**H**)
- Anterior chamber intraocular lens

13 Iris
- Heterochromia
- Iris atrophy/coloboma/corectopia
- Posterior synechiae (**I**)
- Neovascularisation (rubeosis)
- Inflammatory nodules (Koeppe/Busacca)
- Tumours

14 Lens
- Cataract (nuclear sclerotic/cortical/posterior subcapsular)
- Lens subluxation
- Posterior chamber intraocular lens (**J**)

15 Vitreous
- Haemorrhage
- Inflammation
- Asteroid hyalosis

16 Optic disc
- Optic disc swelling (**K**)
- Optic disc cupping (**L**)
- Optic disc pallor

17 Macular
- Drusen
- Hard exudates
- Cotton wool spots
- Retinal haemorrhage (dot/blot/flame shaped)

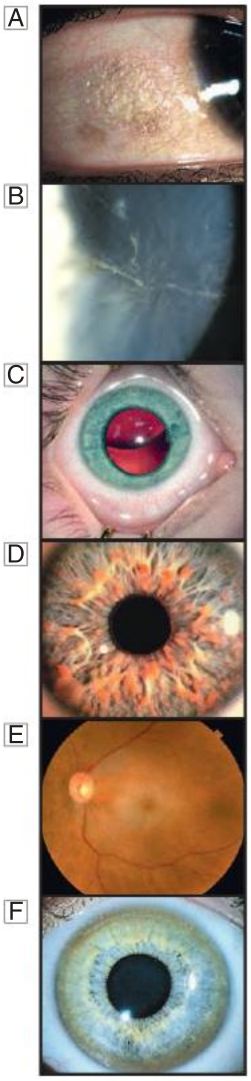
Ocular associations of systemic disease



1 Neurology

Idiopathic intracranial hypertension – Papilloedema.
Migraine – Visual aura, transient visual disturbances.
Multiple sclerosis – Optic neuritis, diplopia, internuclear ophthalmoplegia, uveitis.
Myasthenia gravis – Ptosis, diplopia.
Stroke (cerebrovascular accident) – Visual field defects, gaze palsies.

2 Endocrinology

Diabetes mellitus – Diabetic retinopathy, macular oedema, cataracts.
Pituitary tumours – Bitemporal hemianopia.
Thyroid eye disease (Graves disease) – Proptosis, diplopia, optic neuropathy.

3 Respiratory

Sarcoidosis – Uveitis, optic neuritis, granulomas.
Sleep apnea – Floppy eyelid syndrome, papilloedema due to increased intracranial pressure.

4 Haematology

Anaemia: Retinal haemorrhages, cotton wool spots.
Lymphoma – Adnexal manifestations (orbital/eyelids/lacrimal gland/conjunctiva).
Polycythemia vera – Retinal vein occlusion, retinal haemorrhages.
Sickle-cell disorder – Retinal haemorrhages, proliferative retinopathy, retinal detachment.
Thrombocytopenia – Retinal haemorrhages, subconjunctival haemorrhages.

5 Gastroenterology

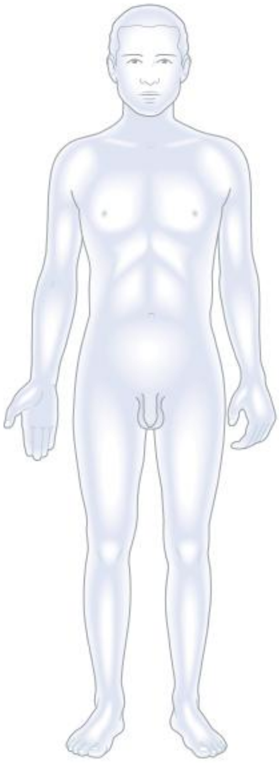
Crohn disease – Uveitis, episcleritis.
Vitamin A deficiency – Night blindness, xerophthalmia (dry eye), Bitot spots (**A**)
Ulcerative colitis – Uveitis, conjunctivitis.

6 Dermatology

Ocular cicatricial pemphigoid – conjunctival scarring, symblepharon formation.
Psoriasis – Anterior uveitis.
Rosacea – Blepharitis, keratitis, conjunctivitis.
Stevens–Johnson syndrome – Severe conjunctivitis, corneal ulceration, scarring.

7 Genetic disorders

Albinism – Nystagmus, depigmented iris, foveal hypoplasia.
Alport syndrome – Lenticonus.
Down syndrome – Brushfield iris spots, cataracts, refractive errors, strabismus.
Fabry disease – Corneal verticillata (**B**), retinal vascular tortuosity, cataracts.
Familial adenomatous polyposis/ Gardner syndrome – Atypical congenital hypertrophy retinal pigment epithelium
Marfan syndrome – Lens subluxation (**C**), myopia, retinal detachment.
Neurofibromatosis type 1 – Lisch nodules (**D**), optic gliomas.
Neurofibromatosis type 2 – Premature cataract, optic nerve sheath meningiomas.
Retinitis pigmentosa – Night blindness, visual field loss.
Tay–Sachs disease – Cherry red spot (**E**)
Tuberous sclerosis – Astrocytic hamartomas.
Usher syndrome – Retinitis pigmentosa.
Von Hippel–Lindau disease – Retinal capillary haemangiomas.
Wilson disease – Kayser–Fleischer rings (copper deposits in the cornea) (**F**)



13 Medication-related

Amiodarone – Corneal verticillata (**B**), optic neuropathy.
Corticosteroids – Raised intraocular pressure (risk of glaucoma), cataract.
Hydroxychloroquine – Bull's eye maculopathy (**G**)
Isotretinoin – Keratitis, idiopathic intracranial hypertension.
Minocycline – Scleral discolouration (**H**)
Sildenafil – Non-arteritic anterior ischaemic optic neuropathy (NAION).
Tamoxifen – Crystalline maculopathy, optic neuritis.

12 Cardiology

Hypertension – Hypertensive retinopathy papilloedema, cotton wool spots.
Endocarditis – Roth spots (**I**)
Atrial fibrillation – Retinal artery occlusion (emboli).
Carotid stenosis – Ocular ischaemic syndrome.
Hypercholesterolaemia – Xanthelasma.

11 Rheumatology

Ankylosing spondylitis – Anterior uveitis.
Behçet disease – Recurrent uveitis, retinal vasculitis.
Giant cell arteritis – Arteritic anterior ischaemic optic neuropathy, central retinal artery occlusion, cranial nerve palsy.
Rheumatoid arthritis – Scleritis (necrotising **J**), episcleritis, keratoconjunctivitis sicca (dry eyes).
Sjögren syndrome – Severe dry eyes, keratitis.
Systemic lupus erythematosus – Retinal vasculitis, optic neuropathy, uveitis.

10 Infectious diseases

Candidaemia – Endogenous endophthalmitis.
Cat scratch disease – Macular star formation (**K**), focal retinopathy.
HIV/AIDS – CMV retinitis, Kaposi sarcoma of the eyelid, cotton wool spots.
HSV/VZV – Acute retinal necrosis, HSV keratitis (**L**)
Malaria – Malarial retinopathy.
Syphilis – Argyll Robertson pupil, interstitial keratitis, uveitis, optic neuritis.
Toxoplasmosis – Retinochoroiditis
Tuberculosis – Uveitis, granuloma, optic neuropathy.

9 Nephrology

Chronic kidney disease – Hypertensive retinopathy, retinal haemorrhages, uraemic optic neuropathy.
Dialysis-related – Hypertensive retinopathy, anterior ischaemic optic neuropathy, band keratopathy.
Nephrotic syndrome – Periorbital oedema, retinal vein occlusions.
Renal hypertension – Accelerated hypertensive retinopathy.
Tubulointerstitial nephritis and uveitis syndrome (TINU) – Anterior uveitis.

8 Oncology

Leukaemia – Retinal haemorrhages, Roth spots, cotton wool spots.
Melanoma – Choroidal melanoma, vitreous metastasis.
Metastatic cancer – Choroidal metastasis, orbital metastasis.

The ability to see is an important aspect of everyday life. Although rarely a cause of mortality, visual impairment can have a profoundly negative impact on socioeconomic status, and the prevalence of blindness is disproportionately increased in less affluent parts of the world. Examination of the eye should be an integral part of clinical assessment.

Abnormalities of the eye can be due to intrinsic ocular abnormalities or can be manifestations of systemic disease. Globally, although refractive errors and cataract remain the main causes of visual impairment, significant progress has occurred in prevention and treatment. Public health measures have reduced diseases of poor hygiene and unclean water, such as trachoma and onchocerciasis, and greater access to surgery has reduced the burden of untreated cataract and glaucoma. However, inherited retinal dystrophies, the leading cause of blindness in working-age people, remains untreatable, and with longevity comes age-related macular degeneration, the leading cause of sight loss in ageing.

Functional anatomy and physiology

Visual pathways, innervation of the eye and the control of eye movement are discussed in Chapter 27.

The eyelids

The eyelids serve essential protective and functional roles, including shielding the eye, distributing the tear film and maintaining ocular surface integrity. Structurally, they consist of tarsal plates containing meibomian glands, the orbicularis oculi muscle (responsible for eyelid closure and innervated by the facial nerve), the levator palpebrae superioris muscle (which elevates the upper eyelid, innervated by the oculomotor nerve), and the Müller muscle (sympathetically innervated, assisting in eyelid elevation). Sensory innervation is provided by the trigeminal nerve, with the ophthalmic (V_1) and maxillary (V_2) divisions innervating the upper and lower eyelids, respectively.

Anatomy of the eye

The eye comprises three principal layers (Fig. 28.1): the outer fibrous tunic (sclera/cornea), the middle vascular tunic (uvea), and the inner neural tunic (retina), each playing distinct roles in maintaining ocular function.

- *Fibrous tunic*. The sclera is a dense, avascular connective tissue providing structural integrity and serves as the attachment site for the extraocular muscles. The cornea is a transparent, avascular structure composed of six layers: the epithelium, Bowman layer, stroma, Dua layer, Descemet membrane and endothelium. It serves as the primary refractive element of the eye, contributing approximately 40 dioptres of the total refractive power.
- *Vascular tunic (uvea)*. The uvea includes the choroid, ciliary body, and iris. The choroid is a highly vascularised tissue rich in melanocytes, which absorb stray light and supply nutrients to the outer retinal layers. The ciliary body comprises the ciliary muscle,

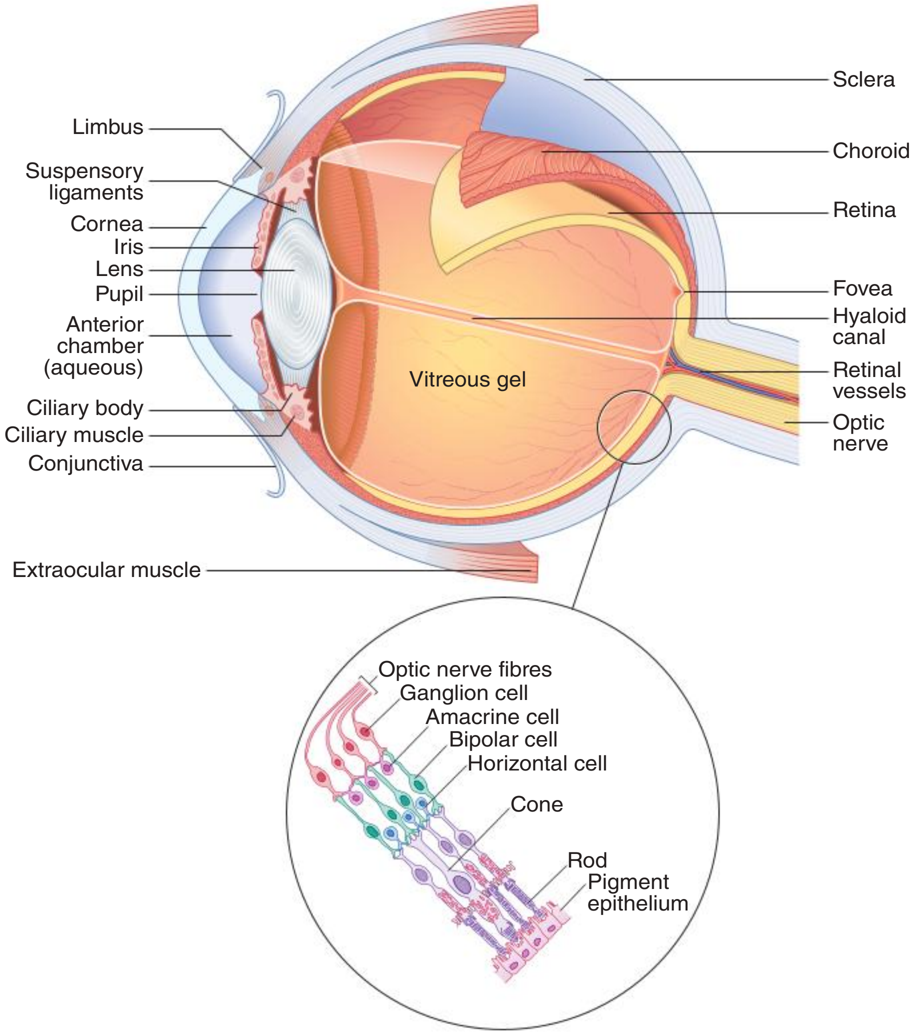

Fig. 28.1 The main structures of the eye. The inset shows the arrangement of the retinal cells. *Inset adapted from Douglas G, Nicol F, Robertson C (eds). Macleod's clinical examination, 13th ed. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2013.*

responsible for lens accommodation, and the ciliary processes, which secrete aqueous humour into the anterior chamber. The iris contains smooth muscle fibres (sphincter pupillae and dilator pupillae) that modulate pupil size, thus controlling the amount of light reaching the retina.

- *Neural tunic (retina)*. The retina is a complex, multi-layered structure where phototransduction occurs. It contains photoreceptors (rods and cones), bipolar cells, ganglion cells, horizontal cells and amacrine cells. The rods are responsible for scotopic (low-light) vision, while cones mediate photopic (daylight) and colour vision, with subtypes sensitive to short (S), medium (M) and long (L) wavelengths of light. The macula, particularly the fovea centralis, contains a high density of cones and is critical for high-resolution central vision.

The orbit

The orbit is a bony cavity that houses and protects the eye, along with its associated structures, including the extraocular muscles, optic nerve, blood vessels and fat. The orbital walls are formed by seven bones: the frontal, sphenoid, zygomatic, maxillary, palatine, lacrimal and ethmoid bones. The orbit's primary function is to protect the eye from trauma and to provide a stable and functional environment for ocular movements.

- *Orbital fat*. Orbital fat cushions the eye within the orbit, allowing for smooth movement and acting as a shock absorber.
- *Orbital blood supply*. The ophthalmic artery, a branch of the internal carotid artery, provides the primary blood supply to the orbit and eye, branching into the central retinal artery, ciliary arteries, and other branches that nourish the ocular structures.
- *Venous drainage*. Venous blood is drained from the orbit via the superior and inferior ophthalmic veins, which empty into the cavernous sinus. This venous network is essential for maintaining proper intraorbital pressure and function.

Lacrimal system

The lacrimal system plays a vital role in the production, distribution, and drainage of tears, which are essential for ocular surface health and vision. Tears provide lubrication, remove debris and contain antimicrobial proteins such as lysozyme.

- *Lacrimal gland*. Located in the superolateral aspect of the orbit, the lacrimal gland produces the aqueous layer of the tear film. Stimulation of the lacrimal gland is primarily mediated by the parasympathetic nervous system via the facial nerve (7th cranial nerve).
- *Tear film*. The tear film comprises three layers: the lipid layer (produced by the meibomian glands), the aqueous layer (from the lacrimal gland), and the mucin layer (from goblet cells in the conjunctiva). This multi-layered structure stabilises the tear film and prevents rapid evaporation.
- *Tear drainage*. Tears drain through the puncta located at the medial canthus of the eyelids into the canaliculi, then into the lacrimal sac, and finally through the nasolacrimal duct into the nasal cavity. Proper functioning of this system is crucial to prevent conditions such as dry eye syndrome or epiphora (excessive tearing).

Extraocular muscles and ocular motility

The eye's movement is controlled by six extraocular muscles: the superior, inferior, medial and lateral rectus muscles, and the superior and inferior oblique muscles (Fig. 28.2). These muscles are innervated by three cranial nerves:

- *Oculomotor nerve* (3rd cranial nerve). Innervates the superior, inferior and medial rectus muscles, as well as the inferior oblique and levator palpebrae superioris muscles.

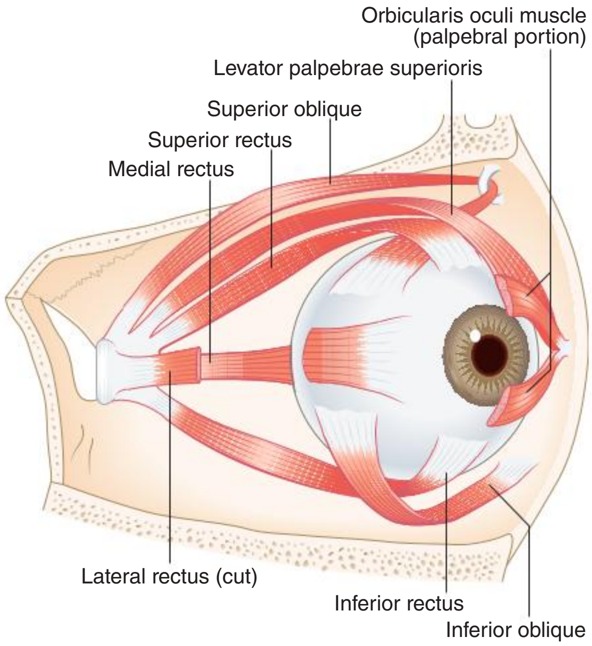

Fig. 28.2 The extraocular musculature (right eye). *Adapted from Batterbury M, Bowling B, Murphy C. Ophthalmology. An illustrated colour text. 3rd ed. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2009.*

- *Trochlear nerve* (4th cranial nerve). Innervates the superior oblique muscle, which intorts and depresses the eye.
- *Abducens nerve* (6th cranial nerve). Innervates the lateral rectus muscle, responsible for abducting the eye.

Coordination of these muscles ensures smooth, precise and conjugate eye movements, allowing for proper alignment of the eyes and enabling binocular vision. Dysfunction in any of these muscles or their innervating nerves can lead to strabismus or diplopia.

Investigation of visual disorders

Ophthalmic investigations encompass a wide range of diagnostic tests and imaging techniques that are essential for the evaluation, diagnosis and management of eye disorders (Fig. 28.3).

Slit-lamp biomicroscopy

Slit-lamp biomicroscopy is a fundamental technique that allows for a detailed examination of the anterior segment of the eye, including the cornea, iris, lens and anterior chamber. To visualise the posterior segment, a fundus lens is used. This allows for a non-contact stereoscopic view of the retina.

Intraocular pressure assessment (tonometry)

Intraocular pressure (IOP) refers to the fluid pressure inside the eye, which is regulated by the balance between the production and drainage of aqueous humour in the anterior chamber of the eye. Normal IOP ranges from 10 to 21 mmHg. Elevated IOP is a significant risk factor for glaucoma, a group of eye diseases that can lead to optic nerve damage and vision loss. The gold standard for measuring IOP is Goldmann Applanation Tonometry. This device is commonly attached on an ophthalmic slit lamp but requires a degree of clinical experience to use. Alternative methods designed for the non-ophthalmologist such as rebound tonometry (e.g. iCare) or non-contract tonometry (the 'air puff test') are useful screening tools. If specialised equipment is not available, a rough IOP estimation can be made by gently

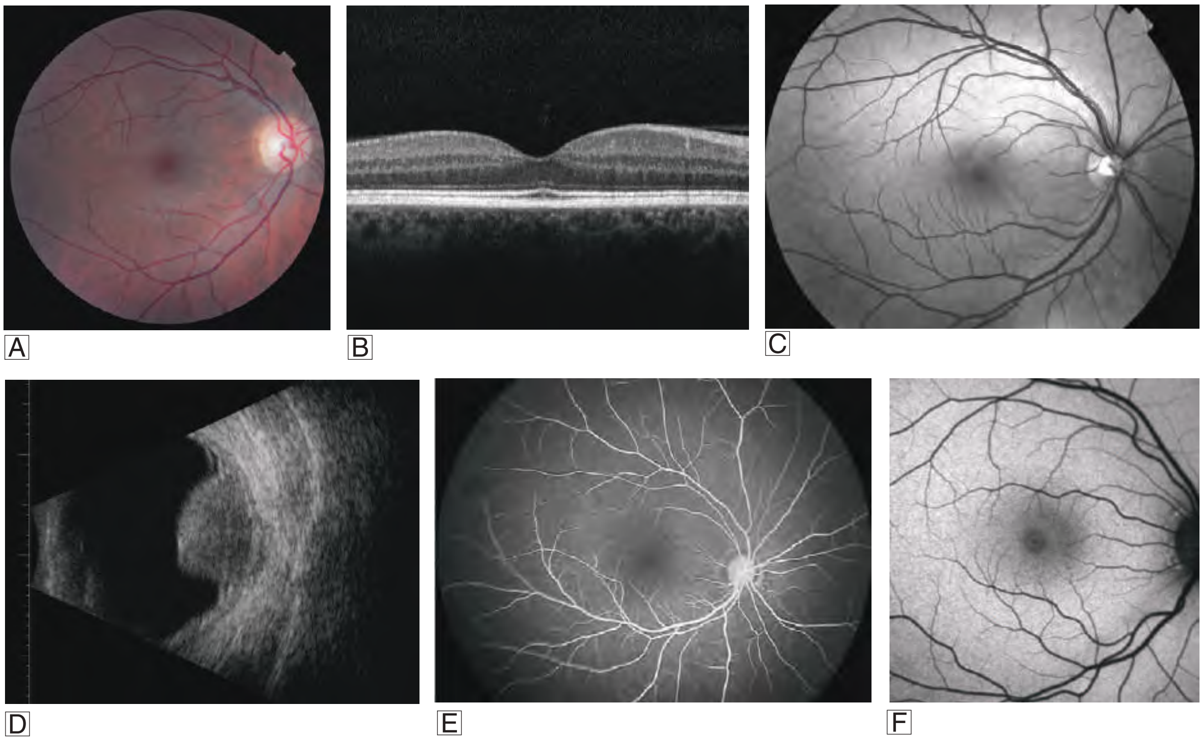

Fig. 28.3 **Ocular imaging.** **A** Colour retinal photograph from a healthy subject. **B** Optical coherence tomogram of a normal eye, showing the layers of the retina. In this image, the macula shows normal foveal indentation. **C** Red-free retinal photograph from a healthy subject. **D** Ocular ultrasound image showing typical biconvex appearance of a choroidal melanoma. **E** Fundal fluorescein angiogram of a normal adult retina. **F** Fundus autofluorescence (FAF) of the right eye in a normal subject. Distribution of FAF intensity shows typical background signal with reduced signal at the optic disc (absence of autofluorescent material) and retinal vessels (absorption). Intensity is markedly decreased over the fovea due to the absorption of the blue light by yellow macular pigment. *(A–D) Courtesy of Aberdeen Royal Infirmary. (E) From Witmer MT, Szilárd K. Wide-field imaging of the retina. Surv Ophthalmol 2013;58(2):143–154. (F) From Schmitz-Valckenberg S, Fleckenstein M, Hendrik PN, et al. Fundus autofluorescence and progression of age-related macular degeneration. Surv Ophthalmol 2009;54(1):96–117.*

palpating the eyeball through the upper eyelid with the index fingers, applying alternating pressure. This technique may help differentiate between a very hard eye with increased IOP, as seen in acute angle closure, and a very soft eye. However, caution should be exercised in cases of suspected ocular injury, especially if perforation is possible.

Optical coherence tomography

Optical coherence tomography (OCT) is a non-invasive imaging modality that provides high-resolution cross-sectional images of the retina, optic nerve and macula. It plays a critical role in diagnosing and monitoring retinal conditions such as age-related macular degeneration, diabetic macular oedema and glaucoma.

Fundus photography

Fundus photography captures detailed images of the retina, optic disc, macula and posterior pole, allowing for documentation and longitudinal comparison of retinal changes over time. Advances in wide-field imaging technology now enable up to 200 degrees of the retina to be photographed in a single image through an undilated pupil.

Fundus angiography

Fundus fluorescein angiography (FFA) involves the intravenous injection of fluorescein dye to visualise the retinal and choroidal vasculature. Indocyanine green angiography (ICGA) uses indocyanine green dye to provide enhanced imaging of the choroidal circulation, making it particularly useful in diagnosing conditions like polypoidal choroidal vasculopathy and uveitis disorders of the choriocapillaris.

OCT angiography (OCTA) is a form of OCT that provides detailed images of the blood flow in the retina and choroid without requiring dye injection. It is particularly useful for assessing macular diseases, such as wet age-related macular degeneration. Because it is non-invasive, OCTA is increasingly being used as an alternative to FFA.

Visual field testing

Visual field testing, such as the Humphrey automated visual field test, is used to assess both peripheral and central vision. Automated perimetry is generally superior to confrontational visual field testing and is considered the gold standard, as it provides a quantitative assessment that allows for tracking changes over time. Visual field defects are often associated with conditions like glaucoma, optic neuropathies and neurological disorders affecting the visual pathway.

B-scan ultrasound

B-scan ultrasound allows visualisation of the posterior segment of the eye when conditions like dense cataracts or vitreous haemorrhages obstruct a direct view.

Electrophysiological tests

Electrophysiological tests, such as electroretinography (ERG) and visual evoked potentials (VEP), assess the electrical responses of the retina and visual pathway to light stimuli, providing valuable insights into retinal and optic nerve function, especially in cases of unexplained vision loss.

Presenting problems in ophthalmic disease

Headache (pp. 222 and 1167), diplopia (p. 1176) and ptosis (p. 1177) are important and common presenting symptoms of ophthalmic disease, although clearly they have a wide differential diagnosis, which is discussed in the indicated chapters.

Acute red eye

Common causes of acute red eye are summarised in Box 28.1. Differentiating the causes of acute red eye is best achieved through a slit-lamp examination, which allows for the identification of intraocular inflammation and the assessment of IOP. In the absence of a slit lamp, serious pathology can typically be identified by screening for reduced visual acuity, elevated IOP, abnormal pupil response to light and corneal pathology. Fluorescein eye drops or fluorets should be used to evaluate the integrity of the ocular surface under cobalt blue light, to detect any epithelial defects or ulcers.

Sudden/subacute loss of vision

Sudden loss of vision is an ophthalmic emergency and should prompt urgent referral to ophthalmology for evaluation. Clinical fundus and optic nerve appearance usually enable the diagnosis to be determined. Common causes are summarised in Box 28.2.

Gradual loss of vision

Gradual loss in vision can be attributed to any ocular structure along the visual pathway, and common causes are summarised in Box 28.3.

Flashes and floaters

Flashes usually result from retinal traction, such as vitreoretinal traction or proliferative retinopathies like diabetic retinopathy or sickle-cell retinopathy. However, flashes can also have neurological causes, including migraine auras or occipital lobe disturbances, which should be considered if retinal pathology is not identified.

Floaters are common and often arise from degenerative changes in the vitreous, like vitreous condensations. They may also occur due to vitreous haemorrhage, which can happen with or without retinal tears. This can be linked to retinal neovascularisation, especially in proliferative diabetic retinopathy, or can be caused by vitritis associated with intermediate or posterior uveitis. Rarely, floaters can indicate more serious conditions, such as lymphoma or amyloidosis.

Flashes and floaters together are most often caused by a posterior vitreous detachment (PVD). A retinal examination should be conducted to exclude any concurrent retinal tears or breaks, which, if untreated, can potentially lead to retinal detachment.

Watery eye (epiphora)

Epiphora, or excessive tearing, can result from three main mechanisms: increased tear production, impaired lacrimal pump function, or decreased tear drainage. These mechanisms can have various causes:

- Increased tear production:
  - Reflex tearing: triggered by local irritation or inflammation, common causes include foreign bodies, conjunctivitis, keratitis or blepharitis.
  - Systemic conditions: diseases like thyroid eye disease (Graves ophthalmopathy) can cause ocular surface irritation and increased tear production.

i 28.1 Common causes of acute red eye

	Acute primary angle closure	Acute anterior uveitis	Corneal abrasion	Keratitis	Anterior scleritis	Episcleritis	Conjunctivitis	Subconjunctival haemorrhage
VA	↓↓↓	↓↓	↓↓	Normal	Normal	Normal	Normal	Normal
Pain	++/+++	++	+++	+/++	++/+++	+	±	Painless
IOP	↑↑↑	Normal/↑	Normal	Normal	Normal	Normal	Normal	Normal
Redness	Diffuse, superficial	Diffuse, superficial	Diffuse, superficial	Diffuse, superficial	Localised, deep	Localised, superficial	Diffuse superficial	Well-defined, confluent area of haemorrhage
Corneal appearance	Hazy secondary to corneal oedema	Normal/KPs	Epithelial defect on fluorescein staining	Infiltrate and surrounding epithelial defect on fluorescein staining	Normal	Normal	Normal	Normal
Pupil	Mid-dilated/ fixed	Small/irregular/ PS	Normal	Normal	Normal	Normal	Normal	Normal
Photophobia	+++	++	++	++	±	Nil	+	Nil
AC cells	Nil/+	+/++/+++	Nil	+/++/+++	Nil	Nil	Nil	Nil
Other features/ symptoms	Extreme pain, opaque cornea, nausea, headache	Previous episodes	Preceding trauma	Prior contact lens use/trauma	Globe tenderness	Redness blanches with topical phenylephrine	Watery discharge/ chemosis (viral) Purulent discharge (bacterial) Papillae/follicles	Prior coughing/ straining
Urgency of definitive diagnosis	Immediate ophthalmology consult	Urgent ophthalmology referral	Urgent ophthalmology referral	Immediate ophthalmology consult	Urgent ophthalmology referral	Urgent ophthalmology referral	Non-emergency	Non-emergency

(AC = anterior chamber; KP = keratic precipitates; IOP = intraocular pressure; PS = posterior synechiae; VA = visual acuity)

28.2 Common causes of sudden/subacute vision loss

	Central retinal artery occlusion	Giant cell arteritis (AAION)	Retinal vein occlusion	Optic neuritis	Vitreous haemorrhage	Amaurosis fugax	Retinal detachment	Wet macular degeneration
Clinical signs	Cherry-red spot macula appearance	Optic disc swelling, cotton wool spots	Retinal haemorrhages, swollen optic disc	Swollen optic nerve (may appear normal if retrobulbar)	Limited fundus view (variable due to extent of haemorrhage)	Normal fundus appearance	Elevated retina on fundoscopy	Macular haemorrhage, subretinal fluid, intraretinal fluid
Pupillary reactions	RAPD	RAPD	Normal pupillary responses	RAPD	Normal pupillary responses	Normal pupillary responses	Normal pupillary responses	Normal pupillary responses
Speed of onset	Seconds to minutes	Seconds to minutes	Hours to days	Hours to days, typically peaking after several days	Depending on extent	Seconds to minutes	Days	Days
Age	Usually, 50–70 years	Unlikely < 50 years, 80% of cases > 70 years	50 years or older	Usually 20–40 years	Variable dependent on underlying pathology	> 50 years	Usually between 40 and 70 years due to PVD	> 50 years
Associated symptoms	Nil	Scalp tenderness, headache, jaw claudication, loss of temporal artery pulsation	Nil	Pain on eye movements Dyschromatopsia	Nil	Nil	Flashers and floaters	Metamorphopsia
Duration	Persistent	Persistent	Persistent	Persistent	Persistent	Transient	Persistent	Persistent
Laterality	Unilateral	Initially unilateral, risk of second eye involvement in delayed diagnosis	Unilateral	Usually unilateral	Unilateral	Unilateral	Unilateral	Unilateral, asynchronous bilateral
Pain	Painless	Painless	Painless	Pain on eye movements	Painless	Painless	Painless	Painless
Associated conditions	Atherosclerosis, atrial fibrillation, hypertension, carotid artery stenosis, GCA	PMR	Hypertension, diabetes mellitus, atherosclerosis	Multiple sclerosis, neuromyelitis optica spectrum disorder	Proliferative diabetic retinopathy, hemorrhagic posterior vitreous detachment, retinal tear	Cardiovascular risk factors, atherosclerosis, diabetes	High myopia, retinitis pigmentosa, Stickler syndrome, Marfan syndrome	Nil
Risk factors	Smoking	80% aged > 70 years. Unlikely in under 50s Female 2.5 times more likely	Increasing age		Trauma		Trauma, age, previous eye surgery	Age, genetic predisposition, smoking, cardiovascular disease
Urgency of definitive diagnosis	Immediate ophthalmology consult	Immediate ophthalmology consult	Urgent ophthalmology referral	Urgent ophthalmology referral	Urgent ophthalmology referral	Urgent ophthalmology referral	Immediate ophthalmology consult	Urgent ophthalmology referral

(AAION = arteritic anterior ischaemic optic neuropathy; GCA = giant cell arteritis; IVMP = intravenous methylprednisolone; PMR = polymyalgia rheumatica; PVD = posterior vitreous detachment; RAPD = relative afferent pupillary defect; US = ultrasound)

- Lacrimal pump failure:
  - Dysfunction in the eyelids or orbicularis oculi muscle impairs tear drainage.
  - Lid laxity: age-related changes can affect eyelid fit, reducing the pump's effectiveness.
  - Orbicularis muscle weakness: often caused by facial nerve palsy, this weakens the lacrimal pump.
- Decreased tear drainage:
  - Obstruction in the tear drainage system reduces outflow.
  - Punctal stenosis: due to ageing, inflammation or eversion of the punctum.
  - Canalicular obstruction: caused by infections, chronic inflammation or trauma.
  - Nasolacrimal duct obstruction: can result from congenital issues, trauma, tumours or chronic inflammation.

Leucocoria in a child

The appearance of a white pupil (leucocoria) in a child, which may sometimes be identified as the lack of a red reflex in photography, requires urgent assessment for the exclusion of retinoblastoma. It typically affects children under 5 years old and can occur in one or both eyes. If left untreated retinoblastoma can be life-threatening. Congenital cataract can also cause leucocoria and may be seen in isolation or associated with a systemic condition, e.g. congenital infections (TORCH – toxoplasmosis, rubella, cytomegalovirus and herpes simplex) or metabolic disorders, e.g. galactosaemia. Other causes include Coats disease, retinal detachment, persistent fetal vasculature or retinal toxocariasis and require evaluation by an ophthalmologist.

i **28.3 Common causes of gradual loss of vision**

	Corneal disease	Refractive error	Keratoconus	Cataract	Optic nerve disease	Glaucoma	Dry AMD
Lens status	Clear	Clear/myopic shift can occur with increasing cataract	Clear	Opacification May cause a myopic shift as progresses	Clear	May have coexistent cataract due to age	May have coexistent cataract due to age
Age	20–30 years	Any	Presentation 10–25 years	Typically > 50 years	Any	Typically > 60 years	Typically > 60 years
Corneal appearance	Abnormal dependent on pathology	Clear	Conical appearance in late disease (Munson sign)	Clear	Clear	Clear	Clear
Macula appearance	Normal	Normal	Normal	Normal	Normal	Normal	Drusen, geographic atrophy
RAPD	Nil	Nil	Nil	Nil	Present	May be present if asymmetrical	Nil
Associated symptoms		Vision improves with pinhole	Can be associated with atopy	Nil	Red desaturation	Nil	Nil
Risk factors	Family history of corneal dystrophy	Family history Prolonged near work (myopia) Ethnicity (East Asian; myopia)	Atopy, eye rubbing	Age, trauma, diabetes, smoking	Nil	Age	Age

(AMD = age-related macular degeneration; RAPD = relative afferent pupillary defect)

Anisocoria

Anisocoria is a condition characterised by unequal pupil sizes, which can be a normal physiological variation or indicate an underlying neurological, ocular or systemic disorder, requiring careful evaluation to determine the cause. Figure 28.4 outlines an approach to determine the underlying cause.

Ophthalmological conditions

Conjunctiva, cornea and sclera

Conjunctivitis

Clinical features

Viral conjunctivitis, frequently caused by adenoviruses, presents with watery discharge, conjunctival injection and often pre-auricular lymphadenopathy. Bacterial conjunctivitis is more commonly associated with purulent discharge, enabling differentiation from viral causes. Bacterial conjunctivitis is commonly secondary to pathogens such as *Staphylococcus aureus* and *Streptococcus pneumoniae*. Allergic conjunctivitis presents with intense itching, tearing and bilateral involvement, often accompanied by chemosis and papillary hypertrophy of the conjunctiva.

Investigations

Diagnosis is typically clinical; however, in cases where the diagnosis is uncertain or if the condition is severe or refractory, additional investigations may be warranted. Conjunctival swabs for Gram staining and culture can aid in identifying bacterial pathogens. Polymerase chain reaction (PCR) testing may be employed for viral identification, particularly in epidemic keratoconjunctivitis. Allergy testing may be considered in cases of chronic or recurrent allergic conjunctivitis.

Management

Management is guided by the underlying cause. Viral conjunctivitis is self-limiting, with treatment focused on symptomatic relief using lubricating eye drops and cool compresses. Bacterial conjunctivitis requires topical antibiotics, such as chloramphenicol to reduce the duration of symptoms and transmission. Allergic conjunctivitis is managed with topical antihistamines, mast cell stabilisers or glucocorticoids in severe cases. Preventive measures include strict hand hygiene and avoidance of eye rubbing to reduce transmission and exacerbation of symptoms.

Microbial keratitis

Pathogenesis

Microbial keratitis is a serious and potentially blinding condition resulting from infection of the cornea caused by bacteria, fungi, viruses or parasites, leading to corneal ulceration and inflammation. Pathogenesis typically involves a breach in the corneal epithelium, which allows microorganisms to invade and colonise the stroma. Common risk factors include contact lens wear, trauma, ocular surface disease and immunosuppression.

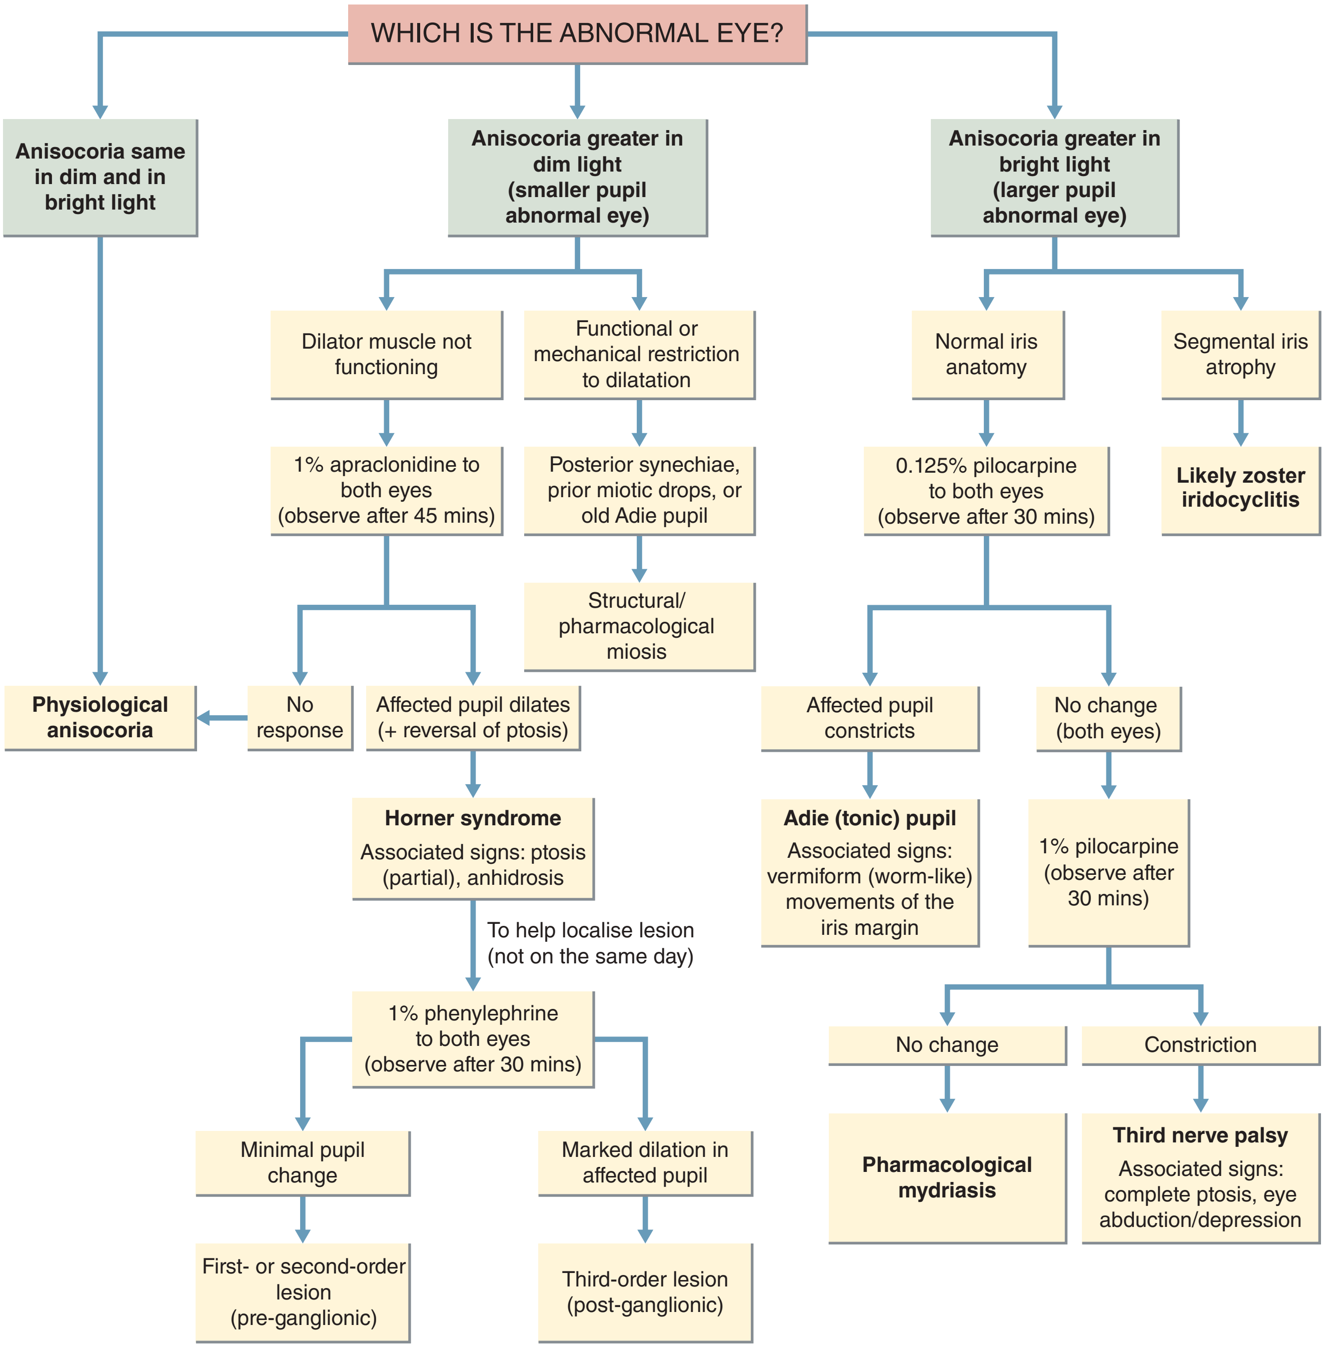
Clinical features

Patients with microbial keratitis often present with acute onset of eye pain, redness, photophobia, blurred vision and discharge.

Central/paracentral ulceration is always more serious than peripheral ulcers due to the involvement of the visual axis and implications for vision. The use of topical fluorescein visualised under cobalt blue light as part of the examination is useful to delineate the extent of corneal epithelial loss.

Bacterial or fungal causes typically have a visible corneal infiltrate or ulcer, accompanied by stromal oedema and anterior chamber inflammation. Severe cases can lead to hypopyon formation (the accumulation of inflammatory cells in the anterior chamber forming a visible layer) and corneal perforation. Differentiation may be challenging clinically. Preceding corneal trauma and contact with soil or plant matter or immunosuppression should raise suspicion of fungal involvement. Rarely, the free-living amoeba *Acanthamoeba castellanii* can be a cause of contact lens–associated keratitis, presenting subacutely with pain out of proportion to clinical signs. It can also lead to corneal nerve infiltration and scleritis, in addition to keratitis.

Herpes simplex keratitis is a common cause of infective keratitis which can involve corneal epithelium, stroma or endothelium. The pathognomonic appearance of a dendritic ulcer and loss of corneal sensation are characteristic of epithelial disease (see p. 1247, image L). In advanced disease, larger 'geographic' ulcers may be visible.



WHICH IS THE ABNORMAL EYE?
Anisocoria same in dim and in bright light
Anisocoria greater in dim light (smaller pupil abnormal eye)
Anisocoria greater in bright light (larger pupil abnormal eye)
Dilator muscle not functioning
Functional or mechanical restriction to dilatation
Normal iris anatomy
Segmental iris atrophy
1% apraclonidine to both eyes (observe after 45 mins)
Posterior synechiae, prior miotic drops, or old Adie pupil
0.125% pilocarpine to both eyes (observe after 30 mins)
Likely zoster iridocyclitis
Structural/ pharmacological miosis
Physiological anisocoria
No response
Affected pupil dilates (+ reversal of ptosis)
Affected pupil constricts
No change (both eyes)
Horner syndrome
Associated signs: ptosis (partial), anhidrosis
Adie (tonic) pupil
Associated signs: vermiform (worm-like) movements of the iris margin
1% pilocarpine (observe after 30 mins)
To help localise lesion (not on the same day)
1% phenylephrine to both eyes (observe after 30 mins)
No change
Constriction
Minimal pupil change
Marked dilation in affected pupil
Pharmacological mydriasis
Third nerve palsy
Associated signs: complete ptosis, eye abduction/depression
First- or second-order lesion (pre-ganglionic)
Third-order lesion (post-ganglionic)

Fig. 28.4 Anisocoria algorithm.

Investigations

Diagnosis is primarily clinical. Differentiation between bacterial and fungal causes requires investigation in the form of corneal scrapings for microscopy, culture and sensitivity testing before empirical treatment is commenced to identify the causative organism, enabling a tailored therapeutic approach. In suspected herpetic disease, corneal swabs for PCR for viral pathogens are useful to confirm the diagnosis. PCR and confocal microscopy are useful in identifying *Acanthamoeba* keratitis. Contact lenses, solutions and cases can also be cultured to aid organism detection if implication is suspected.

Management

For herpetic disease, epithelial involvement can be treated with topical aciclovir 3% ointment/ganciclovir 0.15% gel 5 times daily for 14 days. Topical glucocorticoid use in active epithelial involvement can significantly worsen the disease. Stromal and endothelial involvement require topical glucocorticoids, in addition to antiviral treatment, following the resolution of any epithelial involvement. Long-term oral aciclovir (400 mg twice daily) provides prophylaxis to reduce the frequency of recurrent disease.

Prompt initiation of broad-spectrum empirical topical antibiotics should be commenced for suspected bacterial keratitis. Monotherapy with fluoroquinolones (e.g. ofloxacin, levofloxacin or moxifloxacin) or combined therapy with a cephalosporin (cefuroxime 5%) and fluoroquinolone are common first-line therapies. Treatment is divided into the sterilisation phase – hourly drops for 48 hours – followed by a healing phase where the frequency is reduced. Severe cases or inability to self-administer treatment may require hospitalisation. Regular follow-up is essential to monitor response and prevent complications, which may include corneal perforation.

For fungal keratitis, topical broad-spectrum antifungal agents such as preservative-free clotrimazole 1%, voriconazole 1% or natamycin 5% are initiated hourly for 72 hours. Systemic antifungal treatment should be considered for severe disease. For *Acanthamoeba*, chlorhexidine 0.02% drops and propamidine 0.1% every 2 hours is initial therapy.

Chemical injury

Ocular chemical injuries are serious emergencies that occur when harmful substances come into contact with the eye. These injuries are classified into alkali and acid burns, with alkali burns being more severe due to their ability to penetrate deeper into ocular tissues. Common causative agents include alkalis such as household cleaners (sodium hydroxide, pH 14), plaster (calcium hydroxide, pH 14) and acids such as battery fluid (sulphuric acid, pH 1) and bleach (sodium hypochlorite, pH 1).

Clinical features

Acute symptoms of chemical eye injuries include intense pain, redness, tearing, blurred vision and a sensation of a foreign body in the eye. Clinically, there may be an epithelial defect involving the cornea and affected conjunctiva/sclera. Alkaline burns can lead to increased ocular pressure. Late clinical features include corneal scarring, cicatricial changes, symblepharon formation, dry eye and limbal stem cell deficiency if severe.

Management

The pH of the affected surface should be measured and then topical anaesthetic instilled. If available, a speculum can be inserted and the affected area immediately irrigated with at least 2 litres of water or saline, until the pH is neutralised (normal tears can be slightly alkaline (up to pH 7.4)). The eyelids should be everted to ensure any residual matter is removed. pH testing must be undertaken post-irrigation and again 5 minutes later to ensure stability, and irrigation repeated if the pH is abnormal.

Ophthalmology assessment is paramount to assess the extent of the injury. Treatment depends on severity, but topical antibiotics, cycloplegia (therapeutic pupillary dilatation), topical lubricants and oral analgesia are the mainstay treatment for mild cases. More severe cases may require systemic tetracyclines to prevent tissue necrosis and, in alkali injuries, ascorbic acid may be of additional benefit.

Episcleritis and scleritis

Clinical features

Episcleritis and scleritis are inflammatory conditions of the eye, with episcleritis involving the episclera (the outermost layer) and scleritis affecting the deeper scleral tissues. Episcleritis is typically benign, presenting with mild discomfort, localised redness and no vision loss. It often affects young adults and may be idiopathic or associated with mild systemic conditions. Scleritis is more severe, characterised by intense, deep eye pain, redness with a bluish hue, photophobia and potential vision impairment. Scleritis is commonly associated with systemic autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, or granulomatosis with polyangiitis. It can be either anterior or posterior, and diffuse, nodular or necrotising (with necrotising being the most severe and potentially leading to vision loss).

Investigations

Diagnosis of episcleritis and scleritis is primarily clinical. Episcleritis usually requires no further testing, but recurrent cases may prompt a workup for systemic associations. Blood tests, including full blood count (FBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and specific tests for autoimmune markers (e.g. rheumatoid factor, antinuclear antibodies) may be performed to identify underlying systemic conditions. B-scan ultrasound is useful in cases of posterior scleritis to identify a characteristic thickened choroid and fluid within the episcleral space, extending around the optic nerve ('T sign').

Management

Episcleritis is generally self-limiting, with management focused on symptomatic relief using lubricants or topical non-steroidal anti-inflammatory drugs (NSAIDs).

Treatment of scleritis depends on the severity and underlying cause. Initial management includes systemic NSAIDs or glucocorticoids. In severe cases, immunosuppressive agents such as methotrexate, cyclophosphamide or biologics may be required. Treating the underlying systemic condition is crucial to prevent recurrence and complications.

Peripheral ulcerative keratitis

Clinical features

Peripheral ulcerative keratitis (PUK) is a severe and potentially sight-threatening type of keratitis that involves inflammation and ulceration of the peripheral cornea. It is believed to result from immune complex deposition at the limbus (the border area between the cornea and the sclera), leading to obliterative vasculitis with subsequent corneal thinning and stromal melt. It is commonly associated with systemic autoimmune diseases (see Ch. 25) including rheumatoid arthritis, granulomatosis with polyangiitis, systemic lupus erythematosus, polyarteritis nodosa, relapsing polychondritis and microscopic polyangiitis. Clinically, patients present with symptoms including eye pain, redness, tearing and decreased vision. On examination, there may be conjunctival injection, corneal thinning, ulceration and a crescent-shaped lesion near the limbus. In severe cases, corneal perforation can occur, posing a risk of vision loss.

Investigations

Corneal scraping may be performed to rule out infectious causes. Systemic evaluation is crucial, including blood tests for autoimmune markers (e.g. antinuclear antibodies (ANA), rheumatoid factor, myeloperoxidase (MPO), proteinase 3 (PR3)). Collaboration with a rheumatologist is often necessary for comprehensive evaluation.

Management

Management of PUK involves addressing both the local ocular disease and any underlying systemic condition. Systemic immunosuppressive therapy, such as methotrexate or cyclophosphamide, may be required for underlying autoimmune conditions. In severe cases, surgical intervention like corneal transplantation or amniotic membrane grafting may be necessary to restore corneal integrity.

Cataract

Cataract refers to the opacification of the crystalline lens of the eye, leading to impaired vision.

Cataracts are the leading cause of blindness worldwide, with prevalence increasing significantly with age. The burden of cataract-related visual impairment is particularly pronounced in low- and middle-income countries, where access to surgical intervention may be limited. Age-related cataracts account for the majority of cases, although congenital and secondary cataracts contribute to the overall disease burden. Modifiable risk factors include glucocorticoid use, ocular trauma, ultraviolet (UV) radiation exposure, diabetes and smoking.

Clinical features

Patients with cataracts commonly present with a gradual, painless decline in vision. Symptoms include glare, especially in bright light or while driving at night, diminished visual acuity, halos around lights and difficulty distinguishing colours. The severity and type of visual disturbance depend on the cataract's location and density within the lens. Nuclear sclerotic cataracts often cause myopic shifts, while cortical cataracts may lead to glare and contrast sensitivity issues. Certain systemic conditions are associated with characteristic cataract types, such as 'oil drop' cataracts in galactosaemia, 'sunflower' cataracts in Wilson disease due to copper deposition, and 'Christmas tree' cataracts in myotonic dystrophy (characterised by multi-coloured needle-like inclusions within the lens).

Diagnosis

The diagnosis of cataract may be visual without equipment in severe cases; however, a dilated slit-lamp examination allows for the detailed visualisation of any lens opacity while ruling out other posterior segment pathology that might be contributing to the visual impairment, providing visual prognostic information post-surgery. Additional imaging modalities, such as OCT and B-scan ultrasound, may be employed to further evaluate the posterior chamber in cases where the fundus is not clearly visible.

Management

The definitive management of cataracts is surgical extraction, which is indicated when the cataract impairs daily activities or quality of life. The most common surgical technique is phacoemulsification with intraocular lens (IOL) implantation, which is highly effective but requires expensive, advanced technology and consumables. In resource-limited settings, manual small incision cataract surgery (MSICS) is often utilised, which is less dependent on sophisticated equipment and offers a cost-effective alternative, with outcomes comparable to phacoemulsification in terms of visual rehabilitation.

Retina

Age-related macular degeneration

Epidemiology

Age-related macular degeneration (AMD) is an acquired, degenerative disorder affecting the macula, primarily in adults over 50 years old. Its prevalence increases with age, making it a significant cause of vision impairment in the elderly population.

Pathogenesis

AMD can be categorised into two main forms: dry (atrophic) AMD and wet (neovascular) AMD. Dry AMD, the more common form, is characterised by subretinal drusen deposition, which may lead to blurring and metamorphopsia. As the disease progresses, it can result in loss of the retinal pigment epithelium (geographic atrophy), causing scotomas that may involve the central vision. Neovascular AMD involves choroidal neovascularisation, where abnormal blood vessels grow under the retina, leading to leakage, bleeding and scar formation, resulting in rapid vision loss.

Clinical features

Dry AMD typically presents with gradual visual changes such as blurring and distorted vision (metamorphopsia). Geographic atrophy can lead to central scotomas. In contrast, neovascular AMD often presents with a sudden onset of central distortion and visual loss, progressing rapidly over weeks.

Diagnosis and investigations

Dry AMD is diagnosed through clinical examination and imaging techniques like OCT to assess drusen and retinal changes. Neovascular AMD has traditionally been diagnosed with FFA to identify areas of choroidal neovascularisation. However, OCT and OCTA are increasingly used, enabling non-invasive cross-sectional imaging of the macula, helping differentiate AMD from other retinal pathologies and monitoring the response to therapy.

Management

The management of dry AMD is primarily supportive, focusing on visual aids such as magnifiers, appropriate lighting and specialised adaptations for daily living, along with addressing modifiable risk factors like smoking cessation. Emerging therapies, including intravitreal complement inhibitors, like pegcetacoplan, aim to slow the progression of geographic atrophy but are not yet widely adopted. An Amsler grid can be used for self-monitoring to detect changes that may indicate progression to neovascular AMD.

Neovascular AMD is managed with intravitreal injections of anti-vascular endothelial growth factor (anti-VEGF) agents such as bevacizumab (off-label), ranibizumab, aflibercept and faricimab. These treatments inhibit abnormal blood vessel growth and limit scar formation, significantly improving visual outcomes. However, intravitreal therapy is resource-intensive, requiring regular injections and monitoring to prevent irreversible visual loss due to delayed treatment.

Diabetic eye disease

Epidemiology

Diabetic eye disease, particularly diabetic retinopathy, is one of the most common microvascular complications of diabetes and a leading cause of blindness globally. It affects approximately one-third of individuals with diabetes, with prevalence rates correlating strongly with the duration of the disease and glycaemic control. In patients with type 1 diabetes, nearly all will develop some degree of retinopathy after 20 years, while up to 60% of those with type 2 diabetes may be affected. Key risk factors include poor glycaemic control, hypertension, hyperlipidaemia and nephropathy. Diabetic retinopathy is also more prevalent among certain ethnic groups, including Hispanic and African American populations.

Prevention of diabetic eye disease hinges on meticulous control of diabetes and associated risk factors. Maintaining HbA1c levels below 53 mmol/mol, controlling blood pressure and managing dyslipidaemia significantly reduce the risk of retinopathy progression. The increasing use of advanced technology in type 1 diabetes, such as artificial pancreas systems, may in the future reduce the incidence and severity of diabetic retinopathy, as these systems can significantly improve glycaemic control. Systematic screening for asymptomatic proliferative retinopathy is cost-effective and has led to population-based programmes in many countries. The inclusion of universal OCT scanning has high sensitivity and specificity for detecting diabetic macular oedema. While annual screening is standard, evidence suggests that patients with consistently normal results, especially those with type 2 diabetes, can be screened every two years. Pregnant women should be screened each trimester as increased angiogenic factors and rapid improvement in glycaemic control can lead to a substantial worsening of diabetic retinopathy.

Clinical features

Diabetic retinopathy progresses through stages, beginning with non-proliferative diabetic retinopathy (NPDR), characterised by microaneurysms, retinal haemorrhages, cotton wool spots and hard exudates. As the disease advances to proliferative diabetic retinopathy (PDR), neovascularisation occurs due to retinal ischaemia, leading to fragile new blood vessels that can bleed, causing vitreous haemorrhage and tractional retinal detachment. Diabetic macular oedema (DMO) can occur at any stage and involves the accumulation of fluid in the macula, leading to central vision loss. The pathophysiology involves chronic hyperglycaemia-induced damage to retinal blood vessels, increased vascular permeability and capillary occlusion.

Diagnosis and investigations

Screening programmes for diabetic retinopathy have been established in many countries. Annual or biannual assessment of retinal photographs from non-mydriatic retinal cameras is used to identify possible retinopathy and DMO at an early stage. Formal diagnosis of diabetic eye disease requires a dilated fundoscopic examination to visualise the characteristic retinal vascular changes. Optical coherence tomography (OCT) provides detailed cross-sectional images of the retina, allowing for the detection of macular oedema and its response to treatment. FFA helps to identify areas of retinal non-perfusion and neovascularisation.

Management

Management strategies focus on slowing disease progression and preserving vision. In proliferative diabetic retinopathy, panretinal laser photocoagulation therapy is extremely effective at preserving vision by inducing regression of neovascularisation (Fig. 28.5). Centre-involving diabetic macular oedema is predominantly treated with intravitreal injections of anti-VEGF agents, such as bevacizumab, ranibizumab and aflibercept, which reduce vascular permeability and inhibit abnormal blood vessel growth. In advanced cases, vitrectomy may be necessary to remove non-resolving vitreous haemorrhage or repair tractional retinal detachments.

Retinal vein occlusion

Retinal vein occlusion (RVO) is a common retinal vascular disorder and a significant cause of visual impairment. It occurs due to the blockage of retinal veins, leading to increased venous pressure, haemorrhage and retinal oedema. RVO is classified into two main types: central retinal vein occlusion (CRVO), where the main retinal vein is blocked, and branch retinal vein occlusion (BRVO), affecting one of its smaller branches. Both types can cause vision loss, depending on the extent and location of the occlusion.

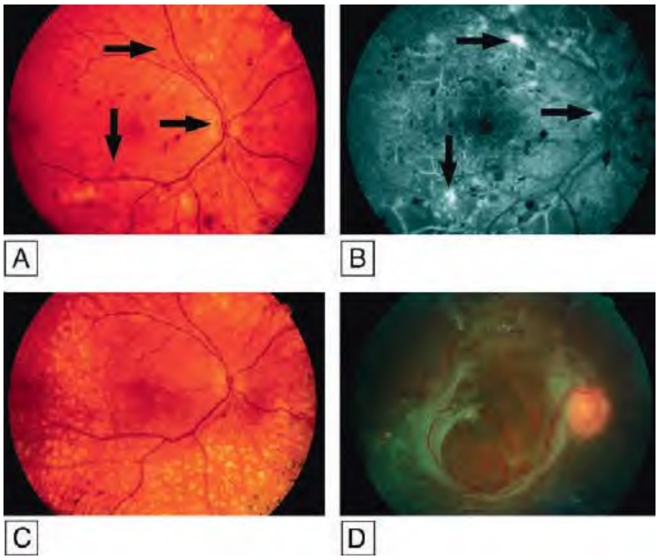


Fig. 28.5 Diabetic retinopathy. Neovascularisation, a hallmark of proliferative diabetic retinopathy (**A**, arrows), which can be identified on fluorescein retinal angiogram (**B**, arrows). **C** Resolution of retinopathy with panretinal photocoagulation. **D** Progression of retinopathy without treatment to fibroproliferative disease. *Adapted from Cheung N, Mitchell P, Wong TY. Diabetic retinopathy. Lancet 2010;376:124–136.*

Epidemiology

RVO is the second most common retinal vascular disease after diabetic retinopathy, affecting approximately 16 million people worldwide. The incidence increases with age, and it is more common in individuals over 50 years. BRVO is more prevalent than CRVO, accounting for about 80% of cases. Risk factors include hypertension, diabetes, hyperlipidaemia and smoking. There is no significant gender predilection, although some studies suggest a slightly higher incidence in males.

Clinical features

Patients with RVO typically present with sudden, painless vision loss or blurring in one eye. CRVO usually results in more severe visual impairment compared to BRVO. Clinical examination may reveal retinal haemorrhages, cotton wool spots, macular oedema and dilated tortuous veins. Neovascularisation and macular oedema are common complications that can further deteriorate vision.

Diagnosis and investigations

Diagnosis is primarily clinical, supported by fundoscopic findings (Fig. 28.6A). Additional imaging, such as fluorescein angiography, is used to assess the extent of retinal ischaemia and leakage, while OCT helps evaluate macular oedema. In younger patients with RVO, further investigations are warranted to rule out underlying systemic conditions such as hypercoagulable states, vasculitis or thrombophilia.

Management

Management of RVO includes intravitreal injections of anti-VEGF agents or glucocorticoids to reduce macular oedema and laser photocoagulation if neovascularisation occurs. Systemic risk factors such as hypertension, diabetes and hyperlipidaemia should be optimally controlled to prevent recurrence or progression.

Retinal artery occlusion

Retinal artery occlusion is a sight-threatening condition caused by the obstruction of the central retinal artery or one of its branches, leading to sudden and severe vision loss. Central retinal artery occlusion (CRAO) affects the entire retina, while branch retinal artery occlusion (BRAO) affects a specific sector of the retina corresponding to the blocked branch. These occlusions are typically due to emboli or thrombi and are associated with cardiovascular risk factors such as hypertension, atherosclerosis and cardiac diseases. Retinal artery occlusion is an ocular

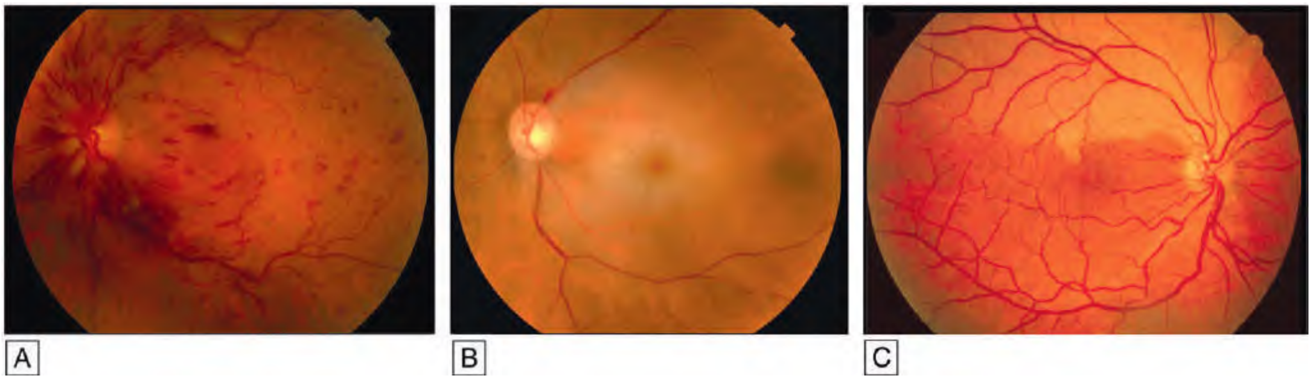

Fig. 28.6 Examples of retinal vascular disease. **A** Colour fundus photograph of a central retinal vein occlusion showing flame haemorrhages and cotton wool spots. **B** Colour fundus photograph of a central retinal artery occlusion showing a classic cherry-red spot and a superior optic disc haemorrhage. **C** Superior branch retinal artery occlusion secondary to an embolus at the optic disc, with corresponding segmental retinal pallor. *(A) From Duker JS, Waheed NK, Goldman DR. Handbook of retinal OCT. Philadelphia: Saunders, Elsevier Inc.; 2014. (B) From Bowling B. Kanski's clinical ophthalmology. 8th ed. Oxford: Elsevier Ltd; 2016.*

emergency, as the retina's limited tolerance to ischaemia can lead to irreversible damage within a short period.

Clinical features

Patients with CRAO typically present with sudden, painless and profound vision loss in one eye, while those with BRAO experience a sudden visual field defect in one eye corresponding to the affected retinal area. On examination, the retina appears pale and swollen, with a characteristic cherry-red spot at the fovea in CRAO (Fig. 28.6B). In BRAO, the pallor and swelling are confined to the specific area supplied by the occluded branch artery (Fig. 28.6C).

Diagnosis and investigations

Diagnosis is primarily clinical, supported by fundoscopic findings. OCT may show retinal oedema. It is crucial to measure ESR and CRP to exclude giant cell arteritis as a cause, especially in patients over 50 years old, given the risk of second eye involvement if missed. Additional investigations include carotid Doppler ultrasound and cardiac evaluation to identify embolic sources.

Management

Management aims to restore retinal perfusion as quickly as possible, as there is a critical window of opportunity – typically 6 hours of onset during which time intervention may improve outcomes. Immediate measures include reducing intraocular pressure through ocular massage, anterior chamber paracentesis or intravenous medications like acetazolamide. While the prognosis for BRAO is generally better than CRAO, rapid intervention remains crucial. Systemic management involves controlling cardiovascular risk factors and considering anticoagulation therapy if indicated. Long-term management focuses on preventing recurrence by addressing underlying systemic conditions and modifying risk factors. If giant cell arteritis is suspected, initiate high-dose glucocorticoids promptly to prevent further vision loss and systemic complications.

Retinal detachment

Epidemiology

Retinal detachment affects approximately 1 in 10 000 people per year. It is more common in individuals over 40, with a higher prevalence in males, those with high myopia, a history of eye surgery (such as cataract removal) or trauma. It is also associated with conditions like lattice degeneration (an abnormally thin retina) and family history.

Pathogenesis

Retinal detachment occurs when the retina separates from the underlying retinal pigment epithelium. This can be due to a tear or hole (rhegmatogenous), traction from scar tissue (tractional) or fluid accumulation beneath the retina (exudative).

Clinical features

Patients typically present with sudden onset of floaters, flashes of light (photopsia) and a shadow or curtain-like effect in their visual field. Vision loss progresses if not treated promptly. Pain is usually absent unless associated with trauma.

Diagnosis

Diagnosis is primarily clinical, confirmed by fundoscopic examination showing an elevated retina with or without tears. B-scan ultrasonography can assist when the view is obscured, such as by vitreous haemorrhage.

Management

Immediate referral to an ophthalmologist is critical. Treatment involves reattaching the retina, typically via procedures like pars planar vitrectomy or scleral buckling. The choice depends on the type and extent of detachment. Intervention prior to macular involvement improves the prognosis for visual recovery.

Miscellaneous retinal manifestations of multisystem disorders

Sickle-cell retinopathy

Clinical features

Sickle-cell retinopathy is a common ocular manifestation in patients with sickle-cell disorder (p. 981), particularly those with haemoglobin SC disorder (HbSC) or HbSβ$^+$ (sickle–beta plus thalassaemia). The condition can present with asymptomatic peripheral retinal changes or progress to vision-threatening complications. Non-proliferative changes include 'salmon patch' haemorrhages, refractile deposits, and 'black sunburst' lesions. Proliferative sickle-cell retinopathy (PSR) is characterised by neovascularisation, which may lead to complications such as vitreous haemorrhage, retinal detachment or neovascular glaucoma. The hallmark of PSR is the 'sea fan' neovascularisation, typically located in the peripheral retina.

Management

Management of sickle-cell retinopathy focuses on early detection and prevention of complications. Regular ophthalmologic evaluations are essential, especially in high-risk patients. For proliferative retinopathy, treatment options include laser photocoagulation to regress neovascularisation, anti-VEGF injections and vitreoretinal surgery in advanced cases with retinal detachment or persistent vitreous hemorrhage. Optimising systemic management of sickle-cell disorder is also crucial in reducing overall disease burden.

Ocular manifestations of von Hippel–Lindau (VHL) disease

Von Hippel–Lindau (VHL) disease (p. 1230) is an autosomal dominant genetic disorder caused by mutations in the *VHL* gene, leading to abnormal blood vessel growth and tumour formation in various organs.

Retinal hemangioblastomas are the most common ocular finding in VHL, appearing as well-defined, orange–red vascular tumours in the retina. They can lead to visual disturbances, including floaters, visual field loss and, if untreated, vision loss due to retinal detachment or macular oedema. Management includes laser photocoagulation, cryotherapy or, in advanced cases, vitreoretinal surgery to preserve vision and prevent complications. Periodic ophthalmic monitoring is crucial.

Ocular manifestations of tuberous sclerosis complex

Tuberous sclerosis complex (TSC), also known as Bourneville disease (p. 1144), is a genetic disorder characterised by the development of benign tumours in multiple organs, including the eyes.

Ocular manifestations in TSC primarily include retinal hamartomas, which are non-cancerous growths that appear as greyish, elevated lesions in the retina. These hamartomas are typically asymptomatic, but can occasionally lead to visual disturbances if they affect the macula or optic nerve. Management is generally conservative, as most retinal hamartomas do not require treatment unless they cause significant visual impairment.

Uveitis

Uveitis is an umbrella term for inflammation anywhere in the uveal tract, retina, choroid or vitreous. The inflammation can be classified based on the location within the eye: anterior, intermediate, posterior or panuveitis. It may result from autoimmune disorders, infections, trauma or exposure to toxins, and it can lead to complications like glaucoma, cataracts, or vision loss if not properly treated.

Anterior uveitis

Anterior uveitis is the most common form of uveitis, characterised by inflammation of the anterior segment of the uveal tract, including the iris and ciliary body. Causes may be idiopathic, autoimmune or infective. Approximately 50%–70% of patients with anterior uveitis are positive for

HLA-B27. This association is particularly strong in individuals with certain seronegative spondyloarthropathies such as ankylosing spondylitis, reactive arthritis and psoriatic arthritis (Ch. 25). While less common, infective causes may be viral-related (herpes simplex (HSV), varicella zoster (VZV) and cytomegalovirus (CMV)) or bacterial (tuberculosis and syphilis).

Clinical features

Anterior uveitis typically presents with eye pain, redness, photophobia and blurred vision. There may be conjunctival injection, keratic precipitates (small circular deposits on the corneal endothelium composed of inflammatory cells), pupil distortion (secondary to posterior synechiae) and inflammatory cells and flare visible in the anterior chamber on slit-lamp examination. In severe cases, a hypopyon (fluid level of inflammatory cells) may be visible.

Investigations

Diagnosis is primarily clinical, using slit-lamp examination to identify cells and flare. A dilated fundus examination is warranted to ensure the absence of posterior uveitis in all cases. In patients with a history of back pain greater than 3 months, with an age of onset less than 45 years old or joint pains requiring visits to health-care professionals, HLA-B27 testing is warranted, with referral to a rheumatologist if positive. Where clinical features suggest a viral infective cause, anterior chamber paracentesis can be performed for PCR analysis.

Management

Treatment involves glucocorticoid eye drops to reduce inflammation and cycloplegic agents to relieve pain from iris spasm and break posterior synechiae. Specific treatment for infective aetiology is given if identified.

Intermediate uveitis

Intermediate uveitis is a disease entity where the majority of the ocular inflammation is isolated to the vitreous cavity. While approximately a third of cases are idiopathic, multiple sclerosis and sarcoidosis are common systemic associations.

Posterior uveitis

Posterior uveitis refers to inflammation involving the retina, choroid and optic nerve. It is the least common, but most sight-threatening form of uveitis, often resulting in significant visual impairment if not promptly identified and treated. This condition can be associated with various infectious, autoimmune or systemic diseases, and requires a thorough clinical evaluation to determine the underlying cause and guide management. A comprehensive review of the forms of posterior uveitis are beyond the scope of this chapter, but notable causes are outlined below.

Ocular tuberculosis

Tuberculosis (TB) is covered in detail in Chapter 17. Ocular extrapulmonary manifestations can occur in approximately 1%–2% of patients; however, in endemic regions and among immunocompromised individuals, the prevalence can be higher. Ocular TB can affect any part of the eye with a varied presentation. Anteriorly, scleritis or anterior uveitis, classically with ‘mutton-fat’ keratic precipitates, can occur. Posterior uveitis manifestations include tuberous choroidal granulomas, retinal vasculitis, multifocal retinitis or serpiginous choroiditis. Management is often in conjunction with respiratory physicians and includes anti-tuberculosis therapy (ATT) for at least 6 to 9 months, with glucocorticoids to control ocular inflammation.

Latent tuberculosis is a particular concern in cases of non-infectious uveitis treated with biologics, which may induce active systemic infection.

Ocular syphilis

Syphilis is covered in detail in Chapter 15. Ocular manifestations of syphilis occur in 1%–5% of syphilis infections and can present at any stage of the disease. Often referred to as ‘the great masquerader’ due to the ability to mimic the signs and symptoms of other diseases, the spectrum of ophthalmic involvement is broad, requiring a high index of suspicion and low threshold for screening, particularly in any cases of bilateral uveitis. Several pathognomonic retinal appearances, termed acute syphilitic posterior placoid chorioretinitis (ASPCC) and syphilitic retinitis, are increasingly well recognised. Other manifestations may include optic neuritis, interstitial keratitis, cranial nerve palsies or light-near dissociation pupil involvement (Argyll Robertson pupil). Co-infection with HIV occurs in around one-third of cases. Ocular involvement should be treated with a neurosyphilis regime as outlined in Chapter 15, which is highly effective.

Ocular toxoplasmosis

Toxoplasmosis is covered in detail in Chapter 14. Ocular toxoplasmosis is the most common cause of posterior uveitis worldwide.

Symptoms vary depending on the severity of the activation and the location of the lesion, but commonly include floaters, blurred vision, photophobia and pain. On examination patients may show characteristic white focal lesions on the retina with overlying vitreous inflammation giving a ‘headlight in the fog’ appearance (Fig. 28.7C). Recurrences commonly occur adjacent to previous pigmented lesions. In the immunocompromised, appearances can vary and mimic acute retinal necrosis in some cases.

Diagnosis is largely clinical. Lesions adjacent to the optic nerve, within the macular or adjacent to the retinal arcades, should be treated in all cases. Due to the toxicity profile of the drugs used, the risks versus benefits of treating peripheral lesions are debatable, but may reduce the risk of recurrence. Treatment typically involves a combination of antiparasitic medication like pyrimethamine and sulfadiazine, along with glucocorticoids to reduce inflammation. There is good evidence that prophylaxis following an activation reduces the risk of further episodes.

Acute retinal necrosis

Acute retinal necrosis (ARN) is a severe viral infection of the retina, typically caused by herpes viruses, herpes simplex virus (HSV) and varicella zoster virus (VZV). It is a rare but potentially blinding condition that primarily affects immunocompetent individuals.

Patients with ARN usually present with symptoms of acute onset of blurred vision, floaters, redness and eye pain. Vision loss can progress quickly. On examination, ARN is characterised by peripheral retinal necrosis, vasculitis and moderate to severe vitritis (see Fig. 28.7A). There may also be involvement of the optic nerve and macula in advanced cases. Delayed retinal detachment can also occur following resolution.

Lymphoma, syphilis and toxoplasmosis in the immunocompromised may mimic the appearance in some cases. Polymerase chain reaction (PCR) of aqueous fluid samples enables the identification of the specific viral pathogen. Intravitreal foscarnet is often undertaken at the time of aqueous sampling, together with oral valaciclovir or intravenous (IV) aciclovir. Early intervention improves the prognosis, but visual outcomes can vary depending on the extent of retinal involvement.

Sarcoidosis

Sarcoidosis is covered in detail in Chapter 17. Ocular manifestations occur in between 25% and 50% of patients with systemic disease. It can involve any part of the eye, with anterior uveitis being the most common form. Other ocular manifestations include conjunctival granulomas, lacrimal gland enlargement, intermediate or posterior uveitis, and retinal vasculitis characterised by periphlebitis with ‘candle-wax drippings’. Optic nerve involvement, scleritis and orbital inflammation are also seen.

Diagnosis is supported by biopsy showing non-caseating granulomas, chest imaging and elevated serum angiotensin-converting enzyme (ACE) levels. Treatment involves glucocorticoids and immunosuppressive agents to manage inflammation.

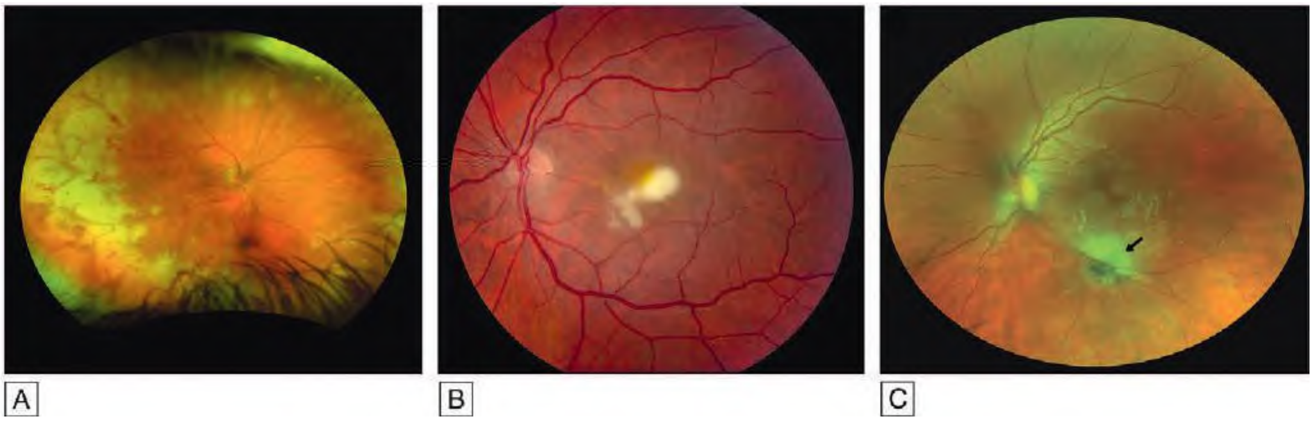

Fig. 28.7 Posterior uveitis entities. A Acute retinal necrosis secondary to varicella zoster virus. B Focal chorioretinitis in clinically suspected endogenous *Candida* endophthalmitis. C Toxoplasmosis chorioretinitis. Arrow highlights active toxoplasma retinochoroiditis adjacent to a pre-existing chorioretinal scar. *(A & C) Courtesy of Princess Alexandra Eye Pavilion. (B) From Ryan SJ (ed). Retina. 5th ed. Philadelphia: Saunders, Elsevier Inc.; 2013 (case courtesy of Jeffrey K. Moore, MD).*

Endophthalmitis

Clinical features

Endophthalmitis is an ocular emergency characterised by marked inflammation of the intraocular cavities, typically secondary to infection. Common clinical features include severe ocular pain, significant reduction in visual acuity, redness and photophobia. On examination, there is often a marked conjunctival injection, corneal oedema and a visible hypopyon in the anterior chamber. The posterior segment may exhibit vitreous opacities, and the red reflex is usually reduced or absent. The condition most frequently arises following intraocular surgery or penetrating trauma (exogenous endophthalmitis), or less commonly from haematogenous spread of systemic infection (endogenous endophthalmitis). The causes of endogenous endophthalmitis are therefore the causes of blood-stream infection (Ch. 14). Gram-positive bacteria are most common, followed by gram-negative bacteria and then fungi, mainly *Candida*, which characteristically causes creamy-white retinal or chorioretinal lesions (see Fig. 28.7B).

Investigations

Diagnostic samples, ideally from both the aqueous and vitreous, should be obtained for Gram stain, culture and sensitivity testing. B-scan ultrasonography serves as an adjunctive tool when direct visualisation of the posterior segment is compromised, identifying features such as dense vitritis or retinal detachment.

Management

Immediate treatment is critical and includes intravitreal administration of broad-spectrum antibiotics, commonly vancomycin and ceftazidime, at the time of diagnostic samples being taken. Pars plana vitrectomy is considered in severe or refractory cases, particularly when the visual prognosis is poor or the infection is unresponsive. Systemic antibiotics may be indicated in cases of endogenous endophthalmitis. The visual prognosis varies significantly and is influenced by the rapidity of diagnosis and intervention, as well as the virulence of the causative organism.

Neuro-ophthalmology

Optic disc swelling

Optic disc swelling can be a developmental variant of normal (pseudopapilloedema), a manifestation of optic nerve pathology or a reflection of more widespread nerve-fibre oedema, as with retinal vein occlusion.

Unilateral optic disc swelling can result from various ocular, neurological and systemic conditions. Key differential diagnoses are shown in Box 28.4.

i 28.4 Causes of optic disc swelling

Local disc swelling	Inflammatory	Optic neuritis Uveitis Posterior scleritis
	Vascular	Central retinal vein occlusion Diabetic papillitis Anterior ischaemic optic neuropathy
	Tumours	Optic nerve meningioma/glioma Orbital tumours
	Infiltrative conditions	Leukaemia Lymphoma
	Granulomatous	Sarcoidosis Tuberculosis
	Compressive optic neuropathies	Orbital tumours Thyroid eye disease
Pseudopapilloedema	Structural causes	Optic disc drusen Tilted discs Myelinated nerve fibres High myopia/high hypermetropia
	Optic disc drusen	Benign but can give visual field defects Visible in fundus autofluorescence/B-scan imaging
Papilloedema	Raised intracranial pressure	Mass effect: space occupying lesion, haemorrhage Decreased CSF drainage: idiopathic intracranial hypertension Increased CSF production: choroid plexus tumour Other: malignancy hypertension

(CSF = cerebrospinal fluid)

Papilloedema

Clinical features

Papilloedema is the swelling of the optic disc secondary to raised intracranial pressure as outlined in Figure 28.8. The extent of papilloedema can be graded on the Frisén scale from 0 to 5 (Box 28.5). Patients may present with symptoms such as headaches, transient visual obscurations, nausea, vomiting and diplopia due to 6th nerve palsy. Visual acuity is typically preserved in the early stages, but prolonged or severe

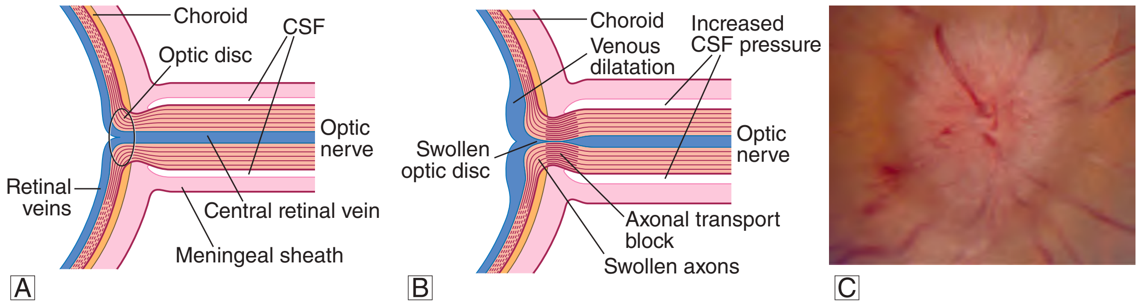

Fig. 28.8 Mechanism of optic disc oedema (papilloedema). **A** Normal. **B** Disc oedema (e.g. due to cerebral tumour). **C** Optic nerve photograph showing marked optic disc oedema (Stage 4 Frisén scale). (CSF = cerebrospinal fluid) *(C) From Liu GT, Volpe NJ, Galetta SL. Liu, Volpe, and Galetta's neuro-ophthalmology: diagnosis and management; ed. 3; Elsevier; 2018.*

i 28.5 Papilloedema grading system (Frisén scale)

Stage 0 – normal optic disc
- No optic disc swelling.
- The disc margins are sharp, and the optic cup is visible.

Stage 1 – very early papilloedema
- C-shaped blurring of the superior and inferior disc margins.
- Subtle elevation of the nasal part of the disc.
- Mild obscuration of the retinal nerve fibre layer (RNFL).

Stage 2 – early papilloedema
- Blurring of all disc margins (not just C-shaped).
- Complete obscuration of the superior and inferior vessels as they leave the disc.
- Peripapillary halo (circular area around the disc) may be seen.

Stage 3 – moderate papilloedema
- More prominent disc elevation.
- Obscuration of all vessels at the disc margin, with vessels buried within the swelling.
- The peripapillary halo is more prominent and extends further from the disc.

Stage 4 – marked papilloedema
- Obscuration of major vessels on the disc surface.
- Nearly total obscuration of the optic cup.
- Increased elevation and extent of peripapillary halo.

Stage 5 – severe papilloedema
- Severe disc swelling with dome-shaped elevation.
- Total obscuration of all vessels originating on the disc.
- Presence of cotton wool spots and hemorrhages near the disc.
- Loss of the optic cup, making the optic disc appear rounded and dome-like.

papilloedema can lead to progressive visual field loss and permanent vision impairment. Fundoscopic examination reveals hyperaemia of the optic disc, blurred disc margins, venous engorgement, haemorrhages and cotton wool spots. Chronic papilloedema may lead to optic atrophy characterised by a pale, shrunken disc.

Investigations

Diagnosis begins with fundoscopy to confirm optic disc swelling. OCT provides detailed imaging of the optic nerve head and retinal nerve fibre layer, aiding in the assessment and monitoring of disc oedema. Optic disc autofluorescence imaging or B-scan ultrasound is useful in excluding optic disc drusen, which may mimic mild papilloedema. Baseline visual field testing helps monitor disease progression. Blood pressure (to exclude hypertensive papillopathy) and calculation of body mass index (as a risk factor for idiopathic intracranial hypertension; p. 1231) should be undertaken.

Urgent computed tomography (CT) head and CT venogram are essential to exclude mass lesions, hydrocephalus or other structural causes of raised intracranial pressure and to exclude venous sinus thrombosis (Ch. 27). A lumbar puncture, performed after imaging, enables the opening pressure to be measured and analysis of the cerebrospinal fluid to exclude infection or inflammation.

Management

Treatment targets the underlying cause of raised intracranial pressure. In idiopathic intracranial hypertension, management includes weight reduction, acetazolamide and diuretics. Refractory cases may require surgical intervention, such as optic nerve sheath fenestration or cerebrospinal fluid shunting. Regular monitoring of visual fields and optic disc appearance is necessary to guide treatment and prevent vision loss.

Giant cell arteritis

Giant cell arteritis (GCA), also known as temporal arteritis, is a chronic vasculitis primarily affecting large and medium-sized arteries, particularly the temporal arteries. Clinical features, diagnosis and management are discussed in Chapter 25. Ocular manifestations include:

- *Visual loss*. Sudden, painless monocular vision loss is a common presentation and is often due to arteritic anterior ischaemic optic neuropathy (AAION), which results from occlusion of the short posterior ciliary arteries. Visual loss in GCA is typically severe and can be permanent if the diagnosis is delayed and treatment is not promptly instituted. Vision loss can also occur secondary to central retinal artery occlusion.
- *Amaurosis fugax*. Some patients may experience transient visual obscurations or episodes of temporary vision loss, known as amaurosis fugax, before permanent visual loss occurs.
- *Diplopia*. Double vision may occur due to ischaemia of the extraocular muscles or their nerve supply, particularly the 3rd cranial nerve.

The vision loss in one eye often precedes similar events in the contralateral eye if the condition remains untreated.

The primary goal in treating GCA is to prevent vision loss and other ischaemic complications. The mainstay of treatment is high-dose glucocorticoids, which should be initiated as soon as GCA is suspected, before a confirmatory temporal artery ultrasound or biopsy is performed. Steroid-sparing agents like tocilizumab (an IL-6 receptor antagonist) are sometimes used in patients requiring prolonged treatment. With prompt diagnosis and treatment, the prognosis for GCA has improved significantly, especially regarding the prevention of vision loss. However, relapses are common, and long-term follow-up is necessary. Approximately 15%–20% of patients may experience permanent visual impairment.

Non-arteritic anterior ischaemic optic neuropathy

Clinical features

Non-arteritic ischaemic optic neuropathy (NAION) typically presents in adults over 50 years old with sudden, painless, monocular vision loss. This vision loss often occurs upon waking and can range from mild to severe. Visual field defects are common, most notably altitudinal defects, although other patterns can occur. Patients may report blurred vision or a dark spot in their central or peripheral vision. On fundoscopic examination, optic disc oedema is often observed, along with splinter haemorrhages at the disc margin. The affected disc is usually pale and swollen, and the condition is more likely in patients with a 'crowded' optic disc appearance.

Investigations

The diagnosis of NAION is primarily clinical, based on history and fundoscopic findings and the exclusion of GCA given the risk of second eye involvement if missed. Visual field testing typically shows characteristic defects and OCT can be used to assess optic nerve head swelling and retinal nerve fibre layer thickness. Blood tests, including FBC, ESR, CRP (to exclude GCA), HbA1c and lipid profile, with assessment of cardiovascular risk factors, are essential to identify and manage systemic contributors.

Management

There is no definitive treatment for NAION. Management focuses on controlling systemic risk factors such as hypertension, diabetes and hyperlipidaemia to reduce the risk of fellow eye involvement, which occurs in 15%–25% of cases. Although various treatments, including glucocorticoids and antiplatelet therapy, have been studied, none have demonstrated consistent efficacy in altering disease progression.

Optic neuritis

Clinical features

Optic neuritis is an inflammation of the optic nerve that often presents with acute vision loss, usually in one eye. Patients typically experience eye pain, especially with eye movement, and vision loss that progresses over hours to days. Other common symptoms include colour vision deficits, such as difficulty distinguishing reds, and a relative afferent pupillary defect (RAPD) (see p. 691). Visual field defects, such as central scotomas, are also common. Some patients report a history of preceding viral illness, and optic neuritis can be the first presentation of multiple sclerosis (MS; p. 1205).

Investigations

The diagnosis of optic neuritis is primarily clinical, but investigations are important to confirm and assess underlying causes. Magnetic resonance imaging (MRI) of the brain and orbits with gadolinium contrast is the most useful test, showing enhancement of the optic nerve in acute cases. An MRI can also assess for other lesions suggestive of MS.

Management

Mild cases of optic neuritis may be observed for spontaneous recovery. Glucocorticoids may speed up recovery but do not affect the final visual outcome. Intravenous methylprednisolone is typically used for severe cases. If no demyelinating lesions are observed on MRI, approximately 25% of patients with idiopathic optic neuritis develop MS over 15 years. The risk increases to 75% over the same time period if lesions are present on MRI imaging.

Ocular myasthenia gravis

Clinical features

Ocular myasthenia gravis (OMG) is a subtype of myasthenia gravis (Ch. 27) that primarily affects the muscles controlling eye movements and eyelids. It commonly presents with ptosis (drooping of one or both eyelids) and diplopia (double vision) due to weakness of the extraocular muscles. Symptoms may fluctuate in severity and often worsen with fatigue or sustained activity. The condition is usually asymmetrical and patients may notice symptoms more prominently on one side. Despite affecting eye muscles, OMG can potentially progress to generalised myasthenia gravis, involving other muscle groups.

Investigations

Diagnosis of OMG involves clinical evaluation and several diagnostic tests. Ice pack test and rest test are quick bedside tests that can help confirm the diagnosis. Acetylcholine receptor antibody (AChR-Ab) testing is positive in between 50% and 70%. Anti-MuSk antibodies are more common in generalised myasthenia gravis (MG), but if positive in OMG may indicate a higher likelihood of progression to generalised MG. Single-fibre electromyography (SFEMG) is highly sensitive for detecting neuromuscular transmission defects. Repetitive nerve stimulation (RNS) may also be used but is less sensitive for ocular muscles.

Management

Treatment of OMG focuses on improving symptoms and preventing progression. Pyridostigmine, an acetylcholinesterase inhibitor, is often the first-line treatment. Glucocorticoids and other immunosuppressive agents, such as azathioprine, may be used for more severe or refractory cases. Thymectomy is generally reserved for those with thymoma or generalised disease. Eyelid crutches or prisms can be used, respectively, for symptomatic relief of ptosis and diplopia.

Optic atrophy

Optic atrophy refers to the degeneration of optic nerve, leading to optic disc pallor visible on fundoscopy. There are many causes of optic atrophy (Box 28.6). History, examination and specific investigations may help to identify the cause.

28.6 Causes of optic atrophy

Hereditary	Leber hereditary optic neuropathy (LHON) Other mitochondrial disorders Autosomal dominant optic atrophy
Ischaemic	Anterior ischaemic optic neuropathy (AION) Central retinal artery occlusion (CRAO)
Inflammatory/ autoimmune	Optic neuritis (often associated with multiple sclerosis) Neuromyelitis optica (NMO)
Compressive	Extrinsic Pituitary adenoma Craniopharyngioma Meningioma Metastasis Thyroid eye disease Intrinsic Optic nerve glioma Optic nerve sheath meningioma Other Aneurysm Mucocele
Traumatic	Direct optic nerve injury Indirect injury (e.g. blunt trauma leading to haemorrhage or oedema)
Toxic/nutritional	Amiodarone Ethambutol Methanol Lead Tobacco-alcohol amblyopia Methanol poisoning Vitamin B_1, B_2, B_6, B_{12} deficiency Folate deficiency
Infectious	Bacterial – tuberculosis, syphilis Viral – herpes zoster
Degenerative	Glaucoma
Vascular	Central retinal artery occlusion Giant cell arteritis (GCA) Systemic lupus erythematosus (SLE)
Miscellaneous	Chronic papilloedema (leading to optic nerve atrophy) Radiation optic neuropathy

Clinical features

Optic neuropathy refers to damage to the optic nerve, leading to visual impairment. Clinical features include sudden or gradual vision loss, often affecting one eye, and may present as central, peripheral or altitudinal visual field defects. Patients might experience decreased colour vision (dyschromatopsia) and a relative afferent pupillary defect (RAPD) in unilateral or asymmetric cases. Pain, especially with eye movement, is commonly associated with optic neuritis, but not with other types like ischaemic optic neuropathy.

Investigations

Evaluation involves a detailed ophthalmic examination, including visual acuity, colour vision testing and fundoscopy to assess the optic disc. Visual field testing helps identify specific patterns of vision loss. OCT measures retinal nerve fibre layer thickness, aiding in detecting optic nerve damage. Imaging studies like MRI of the brain and orbits are crucial for identifying inflammatory, demyelinating or compressive lesions. Blood tests, including inflammatory markers and specific antibodies, can help diagnose underlying causes like giant cell arteritis or autoimmune conditions.

Management

Treatment depends on the underlying cause. For optic neuritis, high-dose intravenous glucocorticoids may accelerate recovery. Ischaemic optic neuropathy management includes addressing cardiovascular risk factors. In compressive optic neuropathy, surgical intervention may be necessary to relieve pressure on the optic nerve. Long-term management focuses on monitoring vision changes and preventing further damage through the treatment of associated systemic conditions.

Glaucoma

Glaucoma is the second leading cause of blindness worldwide after cataracts. It is a group of eye disorders characterised by progressive optic nerve damage, often associated with elevated IOP. The primary types of glaucoma include primary open-angle glaucoma, angle-closure glaucoma and secondary glaucomas, each with distinct pathophysiological mechanisms.

Primary open angle glaucoma

Primary open-angle glaucoma (POAG) is the most common form of glaucoma and a leading cause of irreversible blindness worldwide. It predominantly affects adults over 40 years of age, with increasing prevalence in older populations. The condition shows a higher prevalence in African and Hispanic populations compared to White Europeans, with African ancestry associated with earlier onset and more rapid progression. A family history of glaucoma, elevated IOP, myopia and systemic conditions such as hypertension and diabetes are recognised risk factors. POAG affects both genders, but there is a slightly higher risk in males.

Clinical features

POAG is characterised by an open anterior chamber angle, optic nerve head changes and visual field loss. It is often asymptomatic in the early stages, with no pain or redness, and vision loss typically begins peripherally, progressing slowly towards central vision. Patients may not notice vision changes until significant optic nerve damage has occurred.

Investigations

Diagnosis of POAG involves a comprehensive eye examination, including IOP measurement using tonometry, pachymetry to measure corneal thickness (which influences IOP readings), gonioscopy to confirm an open angle and optic nerve head evaluation via slit-lamp biomicroscopy or OCT. Automated visual field testing enables a quantifiable comparison of disease progression over time.

Management

Management aims to lower IOP to slow disease progression. Initial treatment with 360° selective laser trabeculoplasty (SLT) can delay the need for topical treatment. Where SLT is unavailable or declined, topical treatment with a prostaglandin analogue is the first-line treatment. Beta-adrenoceptor antagonists (β-blockers), alpha agonists, sympathomimetic and carbonic anhydrase inhibitors are additional options where intraocular pressure is insufficiently controlled. The range of topical glaucoma medication is outlined in Box 28.7. Surgical options are reserved for cases refractory to medical and laser therapies. In mild or moderate glaucoma, minimally invasive glaucoma surgery (MIGS) may be considered. Where greater intraocular pressure reductions are required, trabeculectomy or drainage implants may be considered. Regular monitoring including IOP checks, visual field analysis and optic nerve evaluation is required to adjust treatment as needed.

Acute angle-closure glaucoma

Acute angle-closure glaucoma is an ophthalmic emergency characterised by a sudden increase in IOP due to impaired outflow of aqueous humour through a closed or narrowed anterior chamber angle. Epidemiologically, it predominantly affects older adults, with a higher incidence in females and individuals of Asian and Inuit descent. Risk factors include advancing age, hyperopia, a shallow anterior chamber and a family history of the condition.

Clinical features

Acute angle-closure glaucoma presents with rapid onset of severe ocular pain, headache and decreased visual acuity, often accompanied by halos around lights. Associated systemic symptoms such as nausea and vomiting are common due to the abrupt elevation in IOP. Examination reveals a red eye, corneal oedema leading to a hazy appearance, a mid-dilated and fixed pupil, and a shallow anterior chamber. IOP is markedly elevated, frequently exceeding 40–50 mmHg.

Management

Immediate IOP reduction is required to prevent optic nerve damage and irreversible vision loss. This is initially achieved with intravenous acetazolamide in combination with topical pressure-lowering medication and pilocarpine to induce miosis. Definitive management involves laser peripheral iridotomy to create an alternative aqueous humour outflow pathway, preventing recurrence. In refractory cases, surgical lens extraction may be indicated.

Secondary glaucoma

Secondary glaucomas are a group of eye conditions where increased IOP results from underlying ocular or systemic disorders, leading to optic nerve damage and vision loss. These glaucomas can arise due to various causes, including eye trauma, inflammation (like uveitis), vascular disorders (such as central retinal vein occlusion), medications (like glucocorticoids) or intraocular tumours.

Ophthalmic trauma

Tense orbit

Recognition of a tense orbit (orbital compartment syndrome) and the need for immediate intervention can be vision-saving. Orbital injuries resulting in soft tissue oedema and retrobulbar haemorrhage within the confined bony orbit can increase intraorbital pressure, restricting blood flow and causing irreversible optic nerve injury and sight loss.

Clinical features

Visual acuity will be reduced, but to assess this may require the opening of tense eyelids. Proptosis is often painful, with resistance to retropulsion.

28.7 Drugs commonly used in the treatment of glaucoma

Generic name	Brand	Concentration	Dose	Route	Action
Prostaglandin analogues					
Latanoprost	Xalatan	0.005%	Once daily in the evening	Topical	Increase aqueous outflow (uveoscleral route)
Bimatoprost	Lumigan	0.01%	Once daily in the evening	Topical	
Travoprost	Travatan	0.004%	Once daily in the evening	Topical	
Beta-blockers					
Timolol maleate	Timoptic	0.25%, 0.5%	Twice daily	Topical	Decreases aqueous production
Carbonic anhydrase inhibitors					
Brinzolamide	Azopt	1%	Twice daily (if used alone, 3 times daily	Topical	Decrease aqueous production
Dorzolamide	Trusopt	2%	Twice daily (if used alone, 3 times daily	Topical	
Acetazolamide	Diamox	250 mg	Case dependent	Oral	
Acetazolamide modified-release	Diamox Sequels	250 mg	Case dependent	Oral	
Alpha-2 agonists					
Brimonidine	Alphagan	0.2%	Twice daily	Topical	Decrease aqueous production and increase aqueous outflow (uveoscleral route)
Apraclonidine	Iopidine	0.5%	Three times daily	Topical	
Apraclonidine	Iopidine	1%	Stat dose	Topical	
Miotics					
Pilocarpine	Pilocar, Carpine	1%, 2%, 4% 6%	Up to four times daily	Topical	Increases aqueous outflow (trabecular meshwork) through miosis
Rho kinase (ROCK) inhibitor					
Netarsudil	Rhopressa	0.02%	Once daily in the evening	Topical	Increases aqueous outflow (trabecular meshwork) and reduces episcleral venous pressure
Combination drugs					
Latanoprost–timolol	Xalacom	0.005%/0.5%	Once daily in the morning	Topical	
Bimatoprost–timolol	Ganfort	0.03%/0.5%	Once daily in the morning	Topical	
Travoprost–timolol	Duotrav	0.004%/0.5%	Once daily in the morning	Topical	
Brinzolamide–timolol	Azarga	1%/0.5%	Twice daily	Topical	
Dorzolamide–timolol	Cosopt	2%/0.5%	Twice daily	Topical	
Brimonidine–timolol	Combigan	0.2%/0.5%	Twice daily	Topical	
Brinzolamide–brimonidine	Simbrinza	1.0%/0.2%	Twice daily	Topical	
Netasudil–latanoprost	Rocklatan	0.02%/0.005%	Once daily in the evening	Topical	

Eye pressure is elevated and a relative afferent pupillary defect is present. The diagnosis is largely clinical, as while CT orbital imaging may demonstrate the presence of a retrobulbar haemorrhage, this should not delay performing a lateral canthotomy.

Management

If suspected, lateral canthotomy (incision of the lateral canthal tendon) and cantholysis (disinsertion of the lateral canthal tendon) should be performed. If no improvement, IV acetazolamide and IV mannitol can be used.

Orbit

Orbital cellulitis and preseptal cellulitis

Orbital cellulitis is a serious infection of the tissues surrounding the eye within the orbit. It is often caused by bacterial spread from adjacent structures such as the sinuses. It is an ophthalmic and medical emergency with the potential to cause loss of vision and rarely loss of life if there is extension into adjacent intracranial structures.

Pathogenesis

The infection typically spreads from the paranasal sinuses, most commonly the ethmoid sinus. The most common pathogens are *Staphylococcus aureus*, *Streptococcus* species and anaerobes; in children, *Haemophilus influenzae* type B was historically common, but has decreased due to vaccination.

Clinical features

The distinction between orbital cellulitis and, more commonly, preseptal cellulitis is critical in guiding management. Features to aid differentiation are outlined in Box 28.8. For cases of preseptal cellulitis, investigations are not usually necessary. For all suspected orbital cellulitis, undertake temperature measurement, FBC, blood cultures and CT orbits and sinuses (pre- and post-contrast).

Management

Children less than 2 years old should be treated as orbital cellulitis due to their orbital septum having not fully developed and the associated greater risk of progression. Admit patients suspected of having orbital cellulitis for IV antibiotics (ceftriaxone + metronidazole). Early ophthalmology assessment should be obtained. Ear, nose and throat (ENT) assessment should be arranged to assess for sinus drainage.

Malignancies of the eye

Eyelid malignancies

Skin malignancies are discussed in detail in Chapter 26.

Basal cell carcinoma

Representing approximately 85%–90% of all eyelid cancers, basal cell carcinoma (BCC) is the most prevalent eyelid malignancy. It typically presents as a slow-growing, pearly nodule with rolled edges, often accompanied by ulceration. While BCC rarely metastasises, it can cause extensive local tissue destruction if not treated promptly (see Fig. 26.12).

Squamous cell carcinoma

Accounting for about 5%–10% of eyelid malignancies, squamous cell carcinoma (SCC) is more aggressive than BCC. It presents as a scaly, erythematous lesion with irregular borders and may ulcerate. Unlike BCC, SCC has a higher risk of metastasis to regional lymph nodes and distant organs.

Sebaceous carcinoma

A rare but highly aggressive eyelid malignancy, sebaceous carcinoma arises from the sebaceous glands, commonly in the upper eyelid. It may mimic benign lesions, such as chalazia or blepharitis, causing diagnostic delays. Sebaceous carcinoma has a high recurrence rate and potential for both local invasion and distant metastasis.

i 28.8 Differentiation between orbital and preseptal cellulitis

Clinical feature	Preseptal	Orbital
Fever	Sometimes	Usually
Eyelid swelling +/− erythema	Yes	Yes
Proptosis (look from above)	No	Usually – often subtle
Chemosis	Rarely	Usually
Eye pain/tenderness	Sometimes	Yes, often deep
Painful eye movements	No	Yes
Ophthalmoplegia	No	Usually
Visual acuity reduction	No	Late sign
Colour vision affected	No	Possible

Melanoma

Though rare, melanoma of the eyelid is a highly aggressive cancer with a significant risk of metastasis. It often presents as a pigmented lesion with irregular borders and rapid growth, requiring prompt diagnosis and management (Fig. 28.9B).

Common risk factors for these malignancies include prolonged ultraviolet (UV) exposure, fair skin, advanced age and a history of previous skin cancers.

Ocular surface malignancies

Malignancies of the ocular surface are rare but serious conditions that can affect the conjunctiva, cornea and surrounding tissues. The most common types include squamous cell carcinoma, conjunctival melanoma and lymphoma. Squamous cell carcinoma typically arises from the limbal region and is associated with risk factors such as ultraviolet (UV) radiation, human papillomavirus (HPV) infection and immunosuppression (Fig. 28.9C). Conjunctival melanoma originates from melanocytes and presents as a pigmented lesion, often associated with primary acquired melanosis (PAM). Ocular surface lymphomas, commonly of the mucosa-associated lymphoid tissue (MALT) type, may present as painless, salmon-pink lesions.

Choroidal melanomas

Choroidal melanomas are primary ocular malignancies originating from melanocytes. Choroidal melanoma, the most common intraocular melanoma in adults, often presents asymptomatically but may cause blurred vision, floaters, or flashes. It appears as a pigmented or non-pigmented, dome- or mushroom-shaped lesion with possible subretinal fluid and retinal detachment.

The diagnosis is mainly clinical through examination combined with retinal imaging and ultrasonography to assess the internal characteristics.

The goal of treatment is to preserve life and, where possible, vision. Management depends on tumour size, location and presence of metastases. Options include brachytherapy (radioactive plaques surgically placed on the sclera), external beam radiation therapy and surgical enucleation. Systemic therapy (see p. 1115) may be required for metastatic disease (usually liver).

Ocular metastasis

Ocular metastasis refers to the spread of cancer cells to the eye from a primary tumour located elsewhere in the body, most commonly

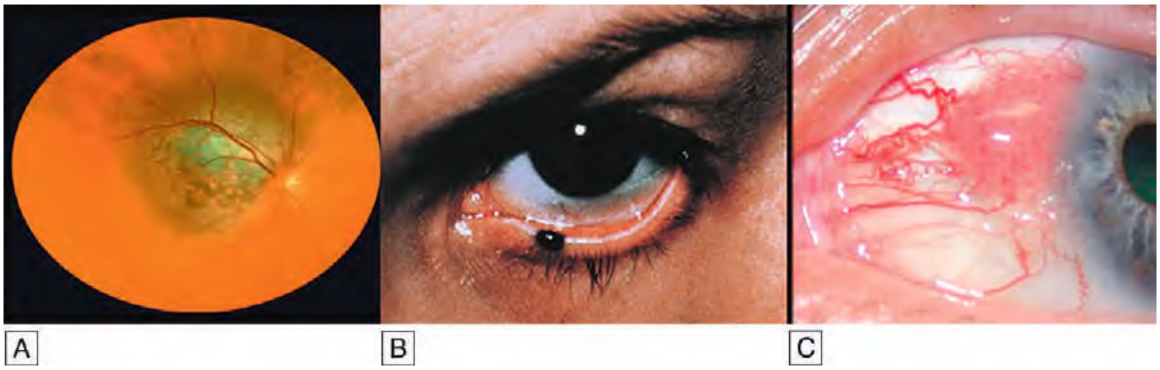

Fig. 28.9 Examples of ocular malignancies. A Choroidal melanoma exhibiting prominent orange pigment (lipofuscin) on its surface. B Eyelid melanoma. C Conjunctival papillomatous squamous cell carcinoma. *(A) From Yanoff M, Duker JS. Ophthalmology. 5th ed. Elsevier; 2019. (B) From Shah JP, Patel SG, Singh B, Wong R. Jatin Shah's head and neck surgery and oncology. 5th ed. Elsevier; 2020. (C) From Yanoff M, Duker JS. Ophthalmology. 4th ed. Elsevier; 2014.*

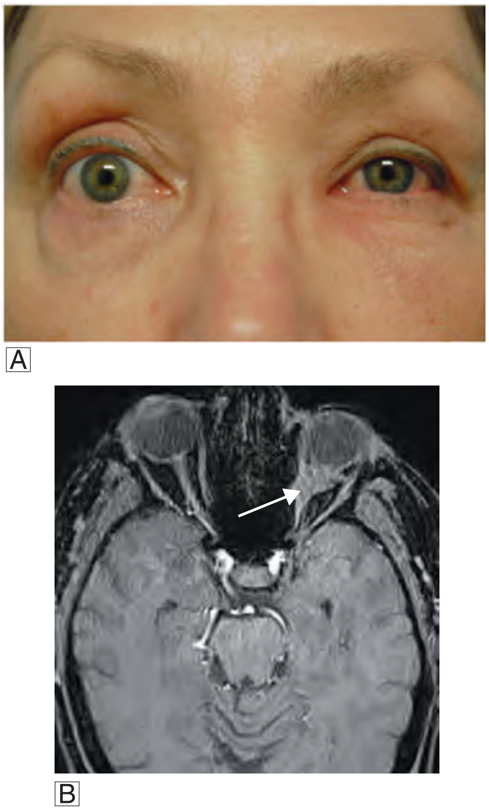

Fig. 28.10 Orbital metastasis from a primary breast cancer. **A** Left eye enophthalmos. **B** Axial T1+ gadolinium sequence MRI of the orbits showing a left-sided infiltrative mass posterior to the globe (arrow) secondary to a metastatic signet ring cell carcinoma. *From Kesting MR, Koerdt S, Rommel N, et al. Classification of orbital exenteration and reconstruction. J Craniomaxillofac Surg. 2017;45(4):467–473.*

originating from the breast or lung. The choroid is the most frequent site of metastasis within the eye due to its rich vascular supply. Metastasis to the orbit can also occur (Fig. 28.10). Symptoms vary depending on location. Retro-orbital locations may cause proptosis and restricted eye movements. Choroidal lesions may cause blurred vision, visual field defects or pain, although some cases are asymptomatic. Diagnosis is typically made through clinical examination, imaging techniques like ultrasound and MRI and sometimes biopsy. Treatment options depend on location but include excision, radiotherapy, chemotherapy and targeted therapies, aiming to preserve vision and control the underlying systemic disease.

Retinoblastoma

Retinoblastoma is the most common malignant intraocular tumour in children, originating from the retinal cells of the eye. It is primarily caused by mutations in the *RB1* gene, either inherited or occurring spontaneously.

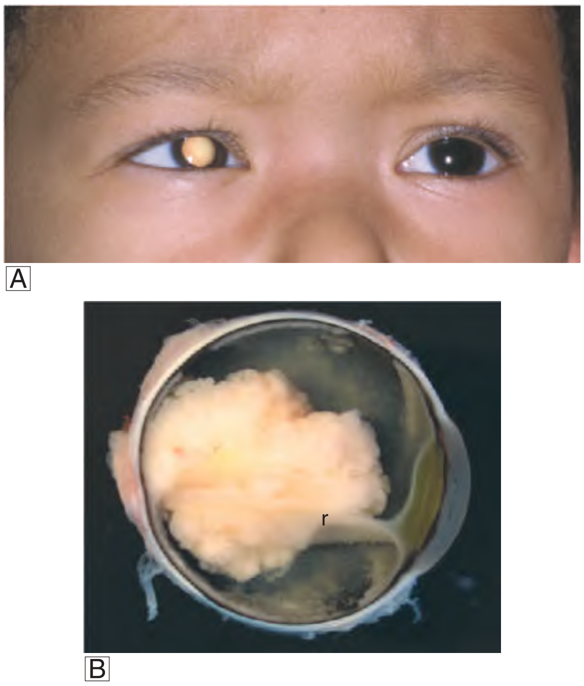

Fig. 28.11 Retinoblastoma in a child. **A** White pupil reflex (leucocoria). **B** Cross-section of enucleated eye specimen. *(A, B) From Jorde LB, Carey JC, Bamshad MJ. Medical genetics. 6th ed. Elsevier; 2020.*

The disease often presents in children under 5 years of age, with symptoms including leucocoria (white pupillary reflex), strabismus, vision loss, or eye redness and swelling. Early diagnosis is critical and is typically made through fundoscopy, ultrasound and MRI. Treatment options vary based on the extent of the disease and may include enucleation, chemotherapy, radiation therapy, laser therapy or cryotherapy, aiming to preserve vision and prevent metastasis (Fig. 28.11).

Multiple Choice Questions

28.1. A 28-year-old man has been referred to eye casualty complaining of a red, watering, painful and photophobic eye for the last 6 days. He is not a contact lens wearer and has been using chloramphenicol ointment from the chemist, which is not improving the symptoms. He has no significant medical history. Examination is challenging due to the degree of photophobia. His eye is very injected with ciliary flush and the pupil reacts sluggishly. What is the most common cause of this condition?

A. Microbial keratitis
B. Episcleritis
C. Angle-closure glaucoma
D. Blepharitis
E. Acute anterior uveitis

Answer: E.

This is a typical presentation of anterior uveitis. Idiopathic anterior uveitis is the most common form. The aetiology is unknown but could be related to cross-reactivity with particular microbial antigens. Systemic associations of anterior uveitis include HLA-B27 spondyloarthropathies, ankylosing spondylitis, psoriatic arthritis and reactive arthritis as well as Crohn disease and ulcerative colitis. Infective causes include *Herpesviridae* herpes simplex and varicella zoster, syphilis, tuberculosis and, rarely, Lyme disease. Other associated systemic conditions include sarcoidosis, juvenile idiopathic arthritis, Behçet disease and systemic lupus erythematosus (SLE). Less common causes include drug-induced, especially anti-cancer drugs, haematological malignancy and even recent tattoos. It is therefore important to take a full systemic history, social and drug history to look for these associations. Microbial keratitis is less likely given the absence of trauma or contact lens use and no corneal infiltrates. Acute angle-closure glaucoma can cause a fixed mid-dilated pupil but is unlikely in this age group. Blepharitis and episcleritis are not typically associated with significant photophobia and would not cause pupillary changes.

28.2. A 35-year-old woman has noticed a change in the appearance of her right eye for the past 5–6 weeks. She describes a slight deterioration in vision and the eye has been aching, which is exacerbated with eye movement. Past medical history includes one spontaneous vaginal delivery and diet-controlled gestational diabetes. She takes the oral contraceptive pill. On examination, visual acuity is 6/12 in the right eye, 6/6 in the left. She has a full range of eye movements but complains of a tugging sensation on upgaze. Her colour vision, visual field testing and pupillary responses are normal. Externally her eyelids are not swollen or red, the eyes are both white. She has 2 mm of proptosis on the right side, and you can see 1 mm of sclera above the cornea. Her basic observations are all within range. What is the most likely diagnosis?

A. Orbital cellulitis
B. Thyroid eye disease
C. Cavernous sinus thrombosis
D. Idiopathic orbital inflammatory syndrome
E. Optic neuritis

Answer: B.

Thyroid eye disease is the most common cause of both unilateral and bilateral proptosis in adults. Typical features include ocular pain at rest, which is exacerbated with eye movements (gaze-evoked pain), swelling and redness of the lids, conjunctiva, plica and caruncle, double vision and proptosis. Sight-threatening complications of thyroid eye disease occur secondary to the increased orbital pressure. If this damages the optic nerve it is termed dysthyroid optic neuropathy, or if orbital swelling causes proptosis so severe that the eyelids cannot close this may result in corneal exposure keratopathy, a potentially sight- and eye-threatening condition. It is always important to consider orbital cellulitis in cases of proptosis, but this would present more acutely with severe lid swelling, oedema, pain and usually with systemic manifestations including pyrexia. The differential diagnosis of proptosis is extensive, including trauma, vascular lesions such as carotid cavernous fistulas or cavernous sinus thrombosis, neoplastic lesions and inflammatory conditions. Optic neuritis can present with reduced visual acuity and retrobulbar pain classically exacerbated with eye movement. However, optic neuritis is not associated with proptosis; additionally, optic nerve function, which includes colour vision, visual field testing and pupillary responses, would be abnormal.

28.3. A 73-year-old man attends his optician. He was hospitalised following a stroke a few months ago, causing weakness in his left face, arm and leg. Although his mobility has improved, he reports his vision on the left is not any better. He wears spectacles for both near and distance and wanted these updating to improve his vision. His past medical history includes atrial fibrillation, hypertension, type 2 diabetes, chronic obstructive pulmonary disease (COPD), hypercholesterolaemia and benign prostatic hyperplasia. The optician performs visual field testing. What is the most likely pattern of visual field loss?

A. Left monocular loss
B. Right homonymous hemianopia
C. Left homonymous hemianopia
D. Bitemporal hemianopia
E. Left superior altitudinal visual field defect

Answer: C.

The left-sided hemiparesis described would be caused by a stroke in the right cerebral hemisphere. The same pathology would affect the right optic radiation. Fibres representing the left temporal hemifield and the right nasal hemifield travel in the right optic radiation. Damage in this area would therefore cause a left homonymous hemianopia. This can be preferentially superior or inferior depending on the particular location of the stroke. Patients may interpret these symptoms and describe it as visual loss from one eye, which is why confrontational visual fields are an important part of a cranial nerve exam. Bitemporal hemianopia is classically caused by pituitary or other chiasmal pathology. Monocular altitudinal visual field defects are caused by pathology affecting the optic nerve or retina.

28.4. A 23-year-old man presents with a two-day history of a red, painful, photophobic left eye. He describes a burning sensation. He has no past ocular history, does not wear contact lenses and is usually fit and well. A drop of fluorescein is instilled into his eye and on examination with blue light a branching dendritic lesion is seen. What is the most appropriate treatment for this condition?

A. Topical aciclovir
B. Oral aciclovir
C. Topical steroid
D. Topical antibiotics
E. Topical lubricants

Answer: A.

A dendritic lesion in the absence of a history of contact lens wear is typical of herpes simplex keratitis. Débridement of the area with a viral swab has a twofold benefit: firstly, it reduces the viral load; and secondly, if it is a first presentation of herpetic eye disease, it is important to establish a formal diagnosis. This is followed by treatment with topical aciclovir until the lesion is resolved. Some types of herpetic eye disease including recurrent presentations benefit from treatment with oral aciclovir. Topical steroid is absolutely contraindicated in the absence of antiviral cover. Topical antibiotics or lubricants will not help because the aetiology is viral.

28.5. A 63-year-old male presents to the emergency department with a 2-day history of left-sided headache and blurring of vision in his left eye for the past 12 hours. He has also noticed pain on chewing and aching in his shoulders. Snellen visual acuities are 6/6 right eye and 6/60 left eye. There is a left afferent pupillary defect, and the left optic disc is swollen. What is the most appropriate first-line investigation for the most likely diagnosis in this presentation?

A. Blood pressure
B. Inflammatory blood markers
C. MRI of the brain
D. Temporal artery biopsy
E. CT head scan

Answer: B.

The diagnosis of highest clinical concern is arteritic anterior ischaemia optic neuropathy secondary to giant cell arteritis (GCA) in this scenario. This diagnosis would be supported by elevated ESR, CRP and a reactive thrombocytosis. Given the end-organ damage, intravenous methylprednisolone should be commenced while awaiting diagnostic confirmation with a temporal artery ultrasound or biopsy. Hypertension is associated with non-arteritic anterior ischaemia optic neuropathy. While high-resolution MRI can detect luminal stenosis or enhancement of the superficial temporal arteries to support a diagnosis of GCA, temporal artery ultrasound, where available, and temporal artery biopsy remain the gold standard of diagnosis.

28.6. A 78-year-old man presents with a decline in his left eye central vision over the past week, making it difficult for him to read and recognise faces. He reports that straight lines appear wavy. He is on medication for hypertension, but this is well controlled. On examination, his vision is 6/9 in his left eye and 6/24 in his right eye. There is no RAPD. He has bilateral nuclear sclerotic cataracts and a cup:disc ratio of 0.6. There are yellow drusen deposits bilaterally but a small haemorrhage at the left macular. What is the most likely diagnosis?

A. Diabetic retinopathy
B. Glaucoma
C. Central retinal vein occlusion
D. Wet age-related macular degeneration
E. Cataracts

Answer: D.

Wet age-related macular degeneration (AMD) is characterised by the gradual loss of central vision, distortion of straight lines and difficulty with tasks requiring detailed vision, such as reading. The presence of drusen and pigmentary changes in the macula are hallmark signs of AMD. The presence of a haemorrhage suggests a choroidal neovascular membrane (wet AMD) which is likely causing disruption of his macula and associated visual changes. Urgent referral to ophthalmology services should be arranged to confirm the diagnosis with OCT and OCTA or fluorescein angiography. Treatment is a course of intravitreal anti-VEGF medication.

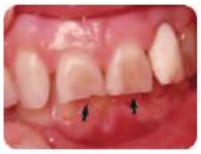
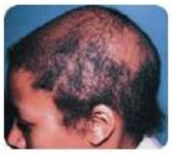
Clinical examination in psychiatric illness

3 Head

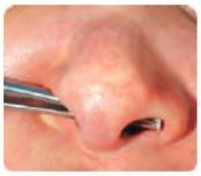
Thin, dry hair – anorexia



▲ Dental erosion/caries – bulimia (self-induced vomiting)



▲ Missing clumps of hair – trichotillomania (hair pulling)



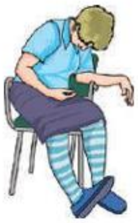
▲ Erosion of nasal septum – cocaine use

2 Behaviour

Agitation/overactivity – anxiety, ADHD, (hypo)mania, acute psychosis/schizophrenia, delirium

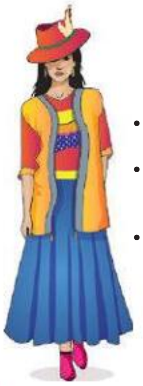
Underactivity – depression, chronic schizophrenia, catatonia, parkinsonism, dementia

Repeating words/postures (echolalia/echopraxia) – autism/catatonia



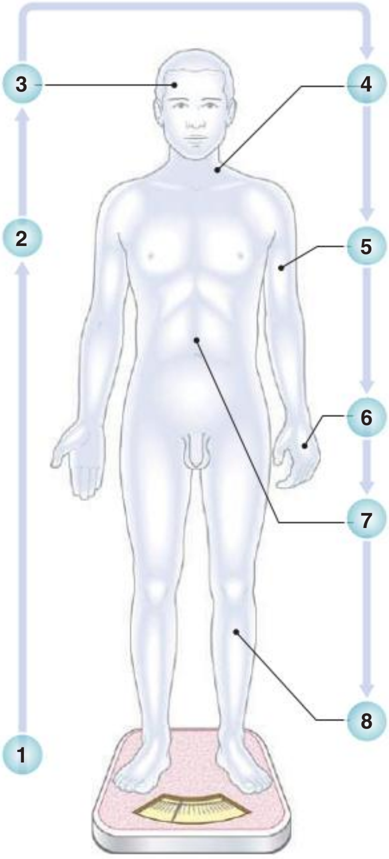
▲ Bizarre postures – catatonia

1 General observations



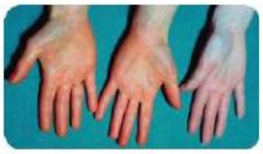
- Endocrine conditions – increased risk of anxiety/depression
- Psychomotor retardation (eyes down, hunched posture, little movement or speech) – depression
- Weight loss – anorexia, depression, dementia

▲ Bizarre/flamboyant dress or demeanour – schizophrenia/(hypo)mania

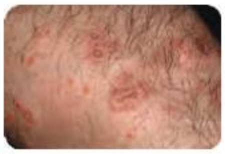


4 Skin

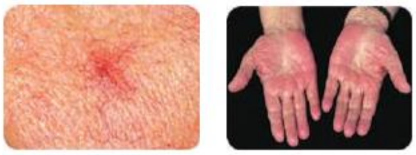
Thin, dry skin, or ‘furry’ skin with lanugo hair – anorexia



▲ Yellow skin (carotenaemia) – anorexia

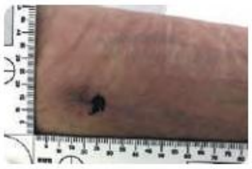


▲ Skin picking/excoriation – OCD



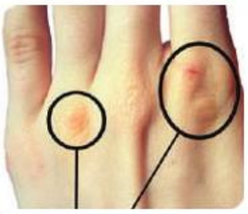
▲ Stigmata of chronic liver disease – spider naevi and palmar erythema

5 Arms

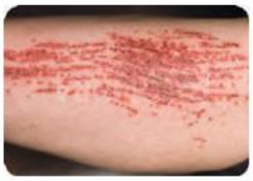


▲ Injection track marks of intravenous drug use and scars from previous self-harm

6 Hands



▲ Knuckle calluses from self-induced vomiting (Russell sign) – bulimia



▲ Contact dermatitis from excessive cleaning/abrasion – OCD

7 Chest/Abdomen

Stigmata of alcoholic liver disease – e.g. gynaecomastia/hepatomegaly/splenomegaly

8 Legs

Peripheral neuropathy – chronic alcohol excess

Psychiatric disorders have traditionally been considered as 'mental' rather than as 'physical' illnesses. This is because they manifest with disordered functioning in the areas of emotion, perception, thinking and memory, and formerly had no clearly biological basis. However, as biochemical and structural abnormalities of the brain are identified in an increasing number of psychiatric disorders, and psychological and behavioural factors are identified in many medical illnesses, the distinction between mental and physical illness has become questionable.

The World Health Organization (WHO) periodically publishes its *International Classification of Diseases* (ICD), which provides definitions for every recognised clinical condition. The 11th Revision (ICD-11, released in 2022) comprises 26 chapters. The diagnoses listed in Chapter 6, 'Mental, behavioural and neurodevelopmental disorders' (Box 29.1), are used by psychiatrists around the world in everyday clinical practice, and it is these conditions that provide the focus for this chapter.

Psychiatric disorders are among the most common of all human illnesses. The WHO's Global Burden of Disease study found 'mental, neurological and substance misuse disorders' to be the leading cause of 'years lost to disability' (YLDs), accounting for almost 20% of global YLDs, with anxiety and mood disorders alone accounting for over 10%. As with most clinical conditions, the prevalence of mental disorders varies with the setting. In the general population, depression, anxiety disorders and adjustment disorders are most common (> 10%) and psychosis is rare (< 2%); in acute medical wards of general hospitals, organic disorders such as delirium are very common, with prevalence highest among sick, older patients; in specialist general psychiatric services, psychoses are the most common disorders (Box 29.2).

29.1 World Health Organization classification of psychiatric disorders (ICD-11)

Chapter 6 (6A0–6E6) **Mental, behavioural and neurodevelopmental disorders**	**Examples**
6A0 Neurodevelopmental disorders	Disorders of intellectual development (learning disability) Autism spectrum disorder (ASD) Attention deficit/hyperactivity disorder (ADHD)
6A2 & 6A4 Schizophrenia and other primary psychotic disorders	Schizophrenia Catatonia
6A6 & 6A7 Mood disorders	Bipolar disorder Depression
6B0, 6B2, 6B4 & 6B6 Anxiety and stress related disorders	Phobias Generalised anxiety disorder Obsessive–compulsive disorder (OCD) Post-traumatic stress disorder (PTSD) Adjustment disorder Dissociative disorders
6B8 & 6C0 Eating and elimination disorders	Anorexia nervosa Bulimia nervosa Enuresis
6C2 Disorders of bodily distress or bodily experience	Bodily distress disorder (somatisation) Bodily integrity dysphoria
6C4 & 6C5 Substance misuse and addiction disorders	Intoxication Harmful use Dependence Withdrawal Substance-related psychosis Gambling disorder
6C7, 6D1 & 6D3 Impulse control, disruptive and paraphilic disorders	Pyromania (fire-setting) Oppositional defiant disorder Paedophilic disorder
6D1 Personality disorders	Dissociality (psychopathy) Anankasia (obsessional personality) Borderline pattern
6D5 Factitious disorders	Factitious disorder imposed on self Factitious disorder imposed on another (by proxy)
6D7 Delirium	Delirium due to medical disease Delirium due to psychoactive substances Delirium due to multiple aetiological factors
6D8 Dementia	Dementia due to Alzheimer disease Dementia due to cerebrovascular disease Dementia due to Lewy body disease Frontotemporal dementia
6E2 Mental disorders associated with pregnancy	Puerperal psychosis Post-partum depression

Adapted from WHO. International Classification of Diseases and Related Health Problems. 11th Revision (ICD-11). Geneva: World Health Organization.

Psychiatric assessment

As in other areas of medicine, the psychiatric assessment comprises a structured clinical history and examination followed by appropriate investigations. However, psychiatric assessment differs from a standard medical assessment in the following ways:

- There is greater emphasis on the history and relatively less reliance on investigations.
- A large part of the clinical examination component is conducted as the history is being taken rather than as a discrete set of procedures afterwards.
- It commonly includes the interviewing of an informant, usually a relative or friend who knows the patient, especially when the illness affects the patient's ability to give an accurate history.

A full psychiatric history (Box 29.3) incorporating a detailed mental state examination may take an hour or more because of its complexity. A brief mental state examination, usually taking no more than a few minutes, should be part of the assessment of *all* patients, not merely those deemed to have psychiatric illnesses.

The psychiatric interview

The aims of the interview are to:

- establish a therapeutic relationship with the patient
- elicit the symptoms, history and background information (see Box 29.3)
- examine the mental state
- provide information, reassurance and advice.

The mental state examination

The mental state examination (MSE) is a systematic examination of the patient's thinking, emotion and behaviour. As with the clinical examination in other areas of medicine, the aim is to elicit objective clinical signs. While many aspects of the patient's mental state may be observed as the

29.2 Prevalence of psychiatric disorders by medical setting

	Medical/surgical			General psychiatric services
	General practice	Outpatients	Inpatients	
Delirium	–	–	+++	–
Alcohol/substance abuse	++	++	+++	+++
Schizophrenia	–	–	–	+++
Bipolar disorder	–	–	–	+++
Depression	++	++	+++	+++
Anxiety disorders	++	++	++	+++
Adjustment disorders	++	++	+++	+
Bodily distress disorders	+	+++	++	–
Personality disorders	+	+	+	+++

– 'rare' (< 2%); + 'uncommon' (2%–5%); ++ 'common' (5%–10%); +++ 'very common' (> 10%).

29.3 How to structure a psychiatric interview

Presenting problem

Reason for referral

- Why the patient has been referred and by whom

Presenting complaints

- The patient should be asked to describe the main problems for which help is requested and what they want the doctor to do

History of present illness

- The patient should be asked to describe the course of the illness from when symptoms were first noticed
- The interviewer asks direct questions to determine the nature, duration and severity of symptoms, and any associated factors

Background

Family history

- Description of parents and siblings, and a record of any mental illness in relatives

Personal history

- Birth and early developmental history, major events in childhood, education, occupational history, relationship(s), marriage, children, current social circumstances

Previous medical and psychiatric history

- Previous health, accidents and operations
- Use of alcohol, tobacco and other drugs
- Direct questions may be needed concerning previous psychiatric history since this may not be volunteered: 'Have you ever been treated for depression or nerves?' or 'Have you ever suffered a nervous breakdown?'

Previous personality

- The patients of behaviour and thinking that characterise a person, including their relationships with other people and reactions to stress (useful information may be obtained from an informant who has known the patient well for many years)

history is being taken, specific enquiries about important features should always be made.

General appearance and behaviour

Any abnormalities of alertness or motor behaviour, such as restlessness or retardation, should be noted. The level of consciousness should be determined, especially in the assessment of possible delirium.

Speech

Speed and fluency should be observed, including slow (retarded) speech and word-finding difficulty. 'Pressure of speech' describes rapid speech that is difficult to interrupt.

Mood

This can be judged by facial expression, posture and movements. Patients should also be asked if they feel sad or depressed and if they lack ability to experience pleasure (anhedonia). Are they anxious, worried or tense? Is mood elevated with excess energy and a reduced need for sleep, as in (hypo)mania?

Thoughts

The content of thought can be elicited by asking 'What are your main concerns?' Is thinking negative, guilty or hopeless, suggesting depression? Are there thoughts of self-harm? If so, enquiry should be made about plans. Are patients excessively worried about many things, suggesting anxiety? Do they think that they are especially powerful, important or gifted (grandiose thoughts), suggesting mania?

The form of thinking may also be abnormal. In schizophrenia, patients may display loosened associations between ideas, making it difficult to follow their train of thought. There may also be abnormalities of thought possession, when patients experience the intrusion of alien thoughts into their mind or the broadcasting of their own thoughts to other people.

Abnormal beliefs

A delusion is a false belief, out of keeping with a patient's cultural background, which is held with conviction despite evidence to the contrary.

Abnormal perceptions

Illusions are misperceptions of real stimuli. Hallucinations are sensory perceptions that occur in the absence of external stimuli, such as hearing voices when no one is present.

Cognitive function

Cognitive function has many components: memory, concentration, visuospatial abilities, executive function and so on. In most cases, a brief assessment of orientation (person, place and time – the patient is asked their name, age, date of birth, what building they are in, the current date and day of the week) and attention ('serial 7 s' – the patient is asked to subtract 7 from 100 and then 7 from the answer, and so on) is sufficient to exclude clinically significant cognitive impairment. Where there is reason to suspect cognitive impairment, a standardised screening tool should be used. In delirium, cognitive impairment typically fluctuates over time so may be missed by a single assessment.

The Montreal Cognitive Assessment (MoCA) is a useful screening questionnaire that covers all the main domains of cognitive function (see p. 1269). It is designed to be easy to use and is freely available online in many different languages. Another widely used screening test is the Mini-Mental State Examination (MMSE), although this is subject to copyright. The Addenbrooke's Cognitive Examination, 3rd edition (ACE-III) offers a more comprehensive assessment and brief training courses for clinicians wishing to use it. These resources are available online (see 'Further information').

Patients' own understanding of their symptoms

Patients should be asked what they think their symptoms are due to and whether they warrant treatment. The failure of a patient to understand their own symptoms is referred to as 'lack of insight'. Psychotic patients characteristically have lack of insight and fail to accept that they are in need of treatment.

Investigations in medical psychiatry

In many areas of medicine, laboratory or radiological tests play a central role in diagnosis. Such tests are often performed in psychiatry but are typically used to exclude non-psychiatric illness rather than to confirm a psychiatric diagnosis. For example, in a patient presenting with symptoms of anxiety, it may be appropriate to check thyroid function to exclude thyrotoxicosis as a cause of their symptoms. Specific investigations are recommended in certain psychiatric conditions, such as dementia, delirium, substance misuse and eating disorders, as shown in Box 29.4. Further details of each of these disorders are discussed later in the chapter.

Functional anatomy and physiology

Most psychiatric disorders result from a complex interplay between psychological, social, environmental and genetic factors. Each of these factors may play a role in predisposing to, precipitating or perpetuating a disorder (Box 29.5).

Biological factors

Genetic

Genetic factors play a predisposing role in many psychiatric disorders, including schizophrenia and bipolar disorder. However, while some disorders, such as Huntington disease, are due to mutations in a single gene, the genetic contribution to most psychiatric disorders is polygenic in nature and mediated by the combined effects of several genetic variants, each with modest effects and modulated by environmental factors.

Brain structure and function

Brain structure is grossly normal in most psychiatric disorders, although abnormalities may be observed in some conditions, such as generalised cerebral atrophy in Alzheimer disease and enlarged ventricles with a slightly decreased brain size in schizophrenia. Functioning of the brain, however, is commonly altered due to changes in neurotransmitters such as dopamine, noradrenaline (norepinephrine) and 5-hydroxytryptamine (5-HT, serotonin). Functional differences in specific areas of the brain are increasingly being recognised using advanced imaging techniques. For example, positron emission tomography (PET) studies of dopamine ligand binding in schizophrenia have consistently demonstrated increased dopamine synthesis in the striatum, even in untreated patients, while a smaller body of PET evidence points towards reductions in 5-HT transporter binding in the mid-brain and amygdala in depression.

Pattern classification approaches to structural magnetic resonance imaging (MRI) data can accurately predict the development of schizophrenia in at-risk populations, while generalised grey matter loss over time is a marker of poor prognosis. Increased anterior cingulate activity in depression is a consistent predictor of good response to both antidepressants and cognitive behaviour therapy. While these and other imaging techniques show potential as diagnostic, prognostic and therapeutic aids, they remain research tools at the present time.

29.4 Investigations in psychiatry

Presentation	Investigation
Dementia	*In most patients* Blood tests: • Full blood count, erythrocyte sedimentation rate, CRP • Urea and electrolytes, calcium, liver function tests, thyroid function tests • HbA$_{1c}$ • Vitamin B$_{12}$ and folate Structural imaging of head (CT and/or MRI) *In selected patients* Further brain imaging: FDG PET or perfusion SPECT, DaTscan, Amyloid/Tau PET Lumbar puncture EEG If clinically indicated, urine microscopy and culture, chest X-ray, ECG, syphilis and HIV serology Very rarely, brain biopsy
Substance misuse	
Alcohol	Breath alcohol FBC U&Es, LFTs, albumin, GGT CT brain* FibroScan*
Other psychoactive substances	Urine drug screen HIV, Hep B, Hep C serology ECG*
Psychosis	Urine drug screen FBC U&Es, TFTs HIV*, syphilis serology* CT brain*
Mood disorders	
Depression	FBC U&Es, TFTs, LFTs Vitamin B$_{12}$*, folate*, vitamin D* EBV serology*
Mania	Urine drug screen FBC U&Es, TFTs CT brain*
Anxiety disorders	FBC U&Es, TFTs, calcium Urine drug screen* GGT* Serum/urine metanephrines
Eating disorders	
Anorexia nervosa	FBC U&Es, TFTs, LFTs, albumin, cholesterol, amylase Calcium, magnesium, phosphate Glucose ECG Bone mineral density scan
Bulimia nervosa	FBC U&Es Calcium, magnesium, phosphate Vitamin B$_{12}$, folate, ferritin ECG

*When indicated in specific cases.
(ANA = antinuclear antibody; anti-dsDNA = anti-double-stranded DNA; CRP = C-reactive protein; CT = computed tomography; DaT = dopamine transporter; EBV = Epstein–Barr virus; ECG = electrocardiogram; EEG = electroencephalogram; ESR = erythrocyte sedimentation rate; FBC = full blood count; FDG PET = fluorodeoxyglucose positron emission tomography; GGT = γ-glutamyl transferase; Hep = hepatitis; HIV = human immunodeficiency virus; LFTs = liver function tests; MRI = magnetic resonance imaging; PET = positron emission tomography; TFTs = thyroid function tests; SPECT = single photon emission computed tomography; U&Es = urea and electrolytes)

29.5 Classification of risk factors for psychiatric disorders

Classification	Examples
Predisposing	
Established in utero or in childhood	Genetic and epigenetic factors Congenital defects
Increase susceptibility to psychiatric disorder	Disturbed family background
Operate throughout patient's lifetime	Chronic physical illness
Precipitating	
Trigger an episode of illness Determine its time of onset	Stressful life events Acute physical illness Misuse of alcohol or drugs
Perpetuating	
Delay recovery from illness	Lack of social support Chronic physical illness

It is also increasingly clear that psychiatric disorders are associated with disruptions in neuronal systems rather than single sites. These can be characterised using diffusion tensor imaging (DTI) of white-matter projection fibres and resting-state/task-based functional MRI (fMRI) studies of inter-regional connectivity. For example, DTI has shown reduced white-matter density in limbic ('emotional') system tracts, such as the fornix and cingulum, in many disorders. Resting-state fMRI studies consistently identify 'default mode', salience and executive control networks of interconnected neuronal populations for certain mental activities. These pathways are implicated in several psychiatric disorders but, as yet, in non-specific ways.

Psychological and behavioural factors

Early environment

Early childhood adversity, such as emotional deprivation or abuse, predisposes to most psychiatric disorders, such as depression, eating disorders and personality disorders in adulthood.

Personality

The relationship between personality and psychiatric disorder can be difficult to assess because the development of psychiatric disorder can impact on a person's personality. Some personality types do predispose to the development of a psychiatric disorder, for example, an obsessional ('anankastic') personality increases the risk of obsessive–compulsive disorder. A disordered personality may also perpetuate a psychiatric disorder once it is established, leading to a poorer prognosis.

Behaviour

A person's behaviour may predispose to the development or perpetuation of a disorder. Examples include excess alcohol intake leading to dependence, dieting in anorexia or persistent avoidance of the feared situation in phobia.

Social and environmental factors

Social isolation

The lack of a close, confiding relationship predisposes to some psychiatric disorders, such as depression, and this may be particularly relevant in older adults where social isolation is common (Box 29.6). As well as predisposing to psychiatric disorders, the reduced social support that results from having a psychiatric disorder may also act to perpetuate it.

Stressors

Social and environmental stressors often play an important role in precipitating psychiatric disorder in those who are predisposed, such as trauma in post-traumatic stress disorder, losses (such as bereavement) in depression, and events perceived as threatening (such as potential loss of employment) in anxiety.

29.6 Medical psychiatry in old age

- **Organic psychiatric disorders**: especially common, so cognitive function should always be assessed; if impaired, an associated medical condition or adverse drug effect should be suspected.
- **Disturbed behaviour**: delirium is the most common cause.
- **Depression**: common. Just because a person is old and frail does not mean that depression is 'to be expected' and that it should not be treated.
- **Self-harm**: associated with an increased risk of completed suicide.
- **Medically unexplained symptoms**: common and often associated with depressive disorder.
- **Loneliness, poverty and lack of social support**: must be taken into consideration in management decisions.

Presenting problems in psychiatric illness

Delirium

Delirium is a medical disorder that is common in older adults and in patients in high-dependency and intensive care units. The causes, assessment and management of delirium are described in Chapter 32.

Alcohol misuse

Misuse of alcohol is a major problem worldwide. It presents in a multitude of ways, which are discussed later on in this chapter and summarised in Box 29.31 below. In many cases, the link to alcohol is obvious; in others, it may not be, since denial and concealment of alcohol intake are common.

Clinical assessment

The patient should be asked to describe a typical week's drinking, quantified in terms of units of alcohol (1 unit contains approximately 8 g alcohol and is the equivalent of half a pint of beer (284 mL), a single measure of spirits or a small glass of wine). The history from the patient may need corroboration by the general practitioner (GP), earlier medical records and family members.

Investigations

Abnormalities in routine biochemistry and haematology can support the diagnosis of alcohol excess (such as the finding of a raised mean cell volume (MCV) and/or raised γ-glutamyl transferase (GGT)), but such tests are abnormal in only half of problem drinkers; consequently, normal results on these tests do not exclude an alcohol problem. When abnormal, these measures may be helpful in challenging denial and monitoring treatment response. Transient elastography (also known as FibroScan) is an ultrasound-based technique that measures fibrosis and steatosis. It is used in specialist services to complement information derived from tests of MCV and GGT.

Management

The prevention and management of alcohol-related problems are discussed later in this chapter.

Substance misuse

The misuse of drugs of all kinds is also widespread. As well as the general headings listed for alcohol problems in Box 29.31 below, additional problems may occur in association with substance misuse (Box 29.7). These can be broken down into two broad categories:

- problems linked with the route of administration, such as intravenous injection
- problems arising from pressure applied to doctors to prescribe the misused substances.

Assessment and management are described later in this chapter in the section on substance misuse.

29.7 Substance misuse

Complications arising from the route of use

Intravenous
- Local: abscesses, cellulitis, thrombosis
- Systemic: bacterial (endocarditis), viral (hepatitis, human immunodeficiency virus (HIV))

Nasal ingestion
- Erosion of nasal septum, epistaxis

Smoking
- Oral, laryngeal and lung cancer

Inhalation
- Burns, chemical pneumonitis, rashes

Pressure to prescribe misused substance
- Manipulation, deceit and threats
- Factitious description of illness
- Malingering

Delusions and hallucinations

Delusions and hallucinations are abnormal beliefs and perceptions that have no rational basis. They are often due to psychiatric illness, but can be secondary to substance misuse, physical illness or neurological disorders, such as epilepsy.

Delusions

A delusion is a false belief, out of keeping with a patient's cultural background, which is held with conviction despite evidence to the contrary. It is common to classify delusions on the basis of their content. They may be:

- persecutory – such as a conviction that others are out to harm one
- hypochondriacal – such as an unfounded conviction that one has cancer
- grandiose – such as a belief that one has special powers or status
- nihilistic – such as 'My head is missing', 'I have no body' or 'I am dead'.

Hallucinations

Hallucinations are defined as sensory perceptions occurring without external stimuli. They can occur in any sensory modality, but most commonly are visual or auditory. Typical examples are hearing voices when no one else is present, or seeing 'visions'. Hallucinations have the quality of ordinary perceptions and are perceived as originating in the external world, not in the patient's own mind (when they are termed 'pseudo-hallucinations'). Those occurring when falling asleep ('hypnagogic') and on waking ('hypnopompic') are a normal phenomenon and not pathological. Hallucinations should be distinguished from illusions, which are misperceptions of real external stimuli (such as mistaking a shrub for a person in poor light).

Clinical assessment

Careful and tactful enquiry is required because agitation, terror or the fear of being thought 'mad' may make patients unable or unwilling to volunteer or describe their abnormal beliefs or perceptions. The nature of hallucinations can be important diagnostically; for example, 'running commentary' voices that discuss the patient are strongly associated with schizophrenia. In general, auditory hallucinations suggest schizophrenia, while hallucinations in other sensory modalities (especially vision but also taste and smell) suggest an organic cause, such as substance misuse, delirium or temporal lobe epilepsy.

Hallucinations and delusions often co-occur. If their content is consistent with coexisting emotional symptoms, they are described as 'mood-congruent'. Thus, patients with severely depressed mood may believe themselves responsible for all the evils in the world, and hear voices saying, 'You are worthless. Go and kill yourself'. In this case, the diagnosis of depressive psychosis is made on the basis of the congruence of different phenomena (mood, delusion and hallucination). Incongruence between hallucinations, delusions and mood suggests schizophrenia.

Investigations

The presence of hallucinations and/or delusions should not automatically trigger a round of investigations. Rather, a careful clinical assessment of the nature, extent and time course of the person's symptoms will generate a list of likely diagnoses, and investigations can then be deployed to differentiate between these. When hallucinations and/or delusions arise in the context of disturbed consciousness and impaired cognition, the diagnosis is usually an organic disorder, most commonly delirium and/or dementia, and should be investigated accordingly.

Management

The management of hallucinations and/or delusions is primarily the management of the underlying condition (such as delirium, schizophrenia, mania or psychotic depression). However, certain principles apply whatever the underlying cause.

Hallucinations and delusions can be very real to, and often frightening for, the person who is experiencing them. They will often seek reassurance from the doctor. The doctor should acknowledge that these experiences are real *for the patient* while avoiding being drawn into colluding with the patient's false beliefs or perceptions. Statements such as 'Sometimes when we are unwell our brain plays tricks on us' can help to reassure a patient. Where the patient lacks insight, however, a more neutral 'We will have to agree to disagree' may be necessary to avoid conflict.

Antipsychotic medication can reduce psychotic symptoms, such as hallucinations and delusion, and is often used in combination with other sedating medication (such as a benzodiazepine) to alleviate acute distress and reduce behavioural disturbance.

Low mood

It is not uncommon for general hospital patients to report low mood. It is important to differentiate an understandable, self-limiting reaction to adversity (such as physical illness or bad news), which is normal and requires support rather than 'treatment', from a depressive disorder, which is characterised by a more severe and persistent disturbance of mood and requires specific treatment.

Clinical assessment

Depression is a relatively common illness, with a prevalence of approximately 5% in the general population and 10%–20% in medical patients. It is important to note that depression has physical as well as mental symptoms (Box 29.8). The diagnosis of depression in the medically ill, who may have physical symptoms of disease such as weight loss, fatigue, disturbed sleep, reduced appetite and so on that overlap with the physical symptoms of depression, relies on detection of the core psychological symptoms of 'anhedonia' (inability to experience pleasure) and the negative cognitive triad (see Box 29.18).

In some cases, depression may occur as a result of a direct effect of a medical condition or its treatment on the brain, when it is referred to as an 'organic mood disorder' (Box 29.9).

29.8 Symptoms of depressive disorders

Psychological
- Depressed mood
- Reduced self-esteem
- Pessimism
- Guilt
- Loss of interest
- Loss of enjoyment (anhedonia)
- Suicidal thinking

Somatic
- Reduced appetite
- Weight change
- Disturbed sleep
- Fatigue
- Loss of libido
- Bowel disturbance
- Motor retardation (slowing of activity)

29.9 Organic mood disorders*

Neurological
- Cerebrovascular disease
- Cerebral tumour
- Multiple sclerosis
- Parkinson disease
- Huntington disease
- Alzheimer disease
- Epilepsy

Endocrine
- Hypothyroidism
- Hyperthyroidism
- Cushing syndrome
- Addison disease
- Hyperparathyroidism

Malignant disease Infections
- Infectious mononucleosis
- Herpes simplex
- Brucellosis
- Typhoid
- Toxoplasmosis

Connective tissue disease
- Systemic lupus erythematosus

Drugs
- Phenothiazines
- Phenylbutazone
- Glucocorticoids, oral contraceptives
- Interferon

*Diseases that may cause organic affective disorders by direct action on the brain.

Investigations

When a patient appears to be low in mood, it is good practice to ask them specifically about their mood. Do they *feel* low (nausea, over-sedation, parkinsonism and so on can all cause a patient to *appear* low in mood). If so, how long have they been feeling low? Are they still able to enjoy things? To what do they attribute their low mood? If the low mood is persistent, not adequately explained by circumstances and/or associated with anhedonia, the patient should be investigated for depression. Where a patient's mood is extremely low, the clinician should ask about suicide. Asking about suicide does not increase the risk of it occurring, whereas failure to enquire denies the opportunity to prevent it. The assessment of suicide risk is described in the self-harm section later in this chapter.

Management

Where a patient's low mood is an understandable reaction to adversity, the clinical team can support the patient by minimising uncertainty through open and effective clinical communication and by addressing isolation (allowing access to visitors, telephone and so on). More details of the strategies available for management of depression are provided later in this chapter.

Elevated mood

Elevated mood is much less common than depressed mood, and in medical settings is often secondary to drug or alcohol misuse, an organic disorder or medical treatment. Where none of these applies, the patient may be experiencing a manic (or, if less severe, 'hypomanic') episode as part of a bipolar affective disorder. Mania is the converse of depression. It may manifest as infectious joviality, over-activity, lack of sleep and appetite, undue optimism, over-talkativeness, irritability, and recklessness in spending and sexual behaviour. When elated mood is severe, psychotic symptoms are often evident, like delusions of grandeur such as believing erroneously that one is royalty.

Investigations

The first investigation for any medical patient presenting with persistent and inexplicable elevated mood in the absence of a history of bipolar affective disorder is a medication review. Mania is a relatively common side-effect of certain classes of drug, such as glucocorticoids, and is a rare side-effect of many other drugs. Recreational, herbal and over-the-counter preparations should also be considered. Second-line investigations include tests for Cushing syndrome, thyrotoxicosis, syphilis and encephalitis.

Management

The management of bipolar disorder and disturbed or aggressive behaviour are discussed in the relevant sections later in this chapter. The management of organic mania involves identifying and addressing the underlying cause.

Anxiety

Anxiety may be transient, persistent, episodic or limited to specific situations. The symptoms of anxiety are both psychological and physical (Box 29.10). The differential diagnosis of anxiety is shown in Box 29.11. Most anxiety is part of a transient adjustment to stressful events: adjustment disorders. Other more persistent forms of anxiety are described in detail on page 1284.

Investigations

Anxiety may occasionally be a manifestation of a medical condition such as thyrotoxicosis (see Box 29.11). Tests to exclude or confirm these conditions should be considered, particularly if anxiety is a new symptom that has arisen in the absence of an obvious stressor.

Management

The management of specific anxiety disorders is discussed later in this chapter. Benzodiazepines and related drugs, while extremely effective in the short term, cause tolerance and unpleasant or even dangerous withdrawal syndromes if used for more than a few weeks.

29.10 Symptoms of anxiety disorder

Psychological
- Apprehension
- Irritability
- Worry
- Poor concentration
- Fear of impending disaster
- Depersonalisation

Somatic
- Palpitations
- Fatigue
- Tremor
- Dizziness
- Sweating
- Diarrhoea
- Frequent desire to pass urine
- Chest pain
- Initial insomnia
- Breathlessness
- Headache

29.11 Differential diagnosis of anxiety

- Normal response to threat
- Adjustment disorder
- Generalised anxiety disorder
- Panic disorder
- Phobic disorder
- Organic (medical) cause:
  Hyperthyroidism
  Paroxysmal arrhythmias
  Phaeochromocytoma
  Alcohol and benzodiazepine withdrawal
  Hypoglycaemia
  Temporal lobe epilepsy

Psychological factors affecting medical conditions

Psychological factors may influence the presentation, management and outcome of medical conditions. Specific factors are shown in Box 29.12. The most common psychiatric diagnoses in the medically ill are anxiety

29.12 Risk factors for psychological problems associated with medical conditions

- Previous history of depression or anxiety
- Lack of social support
- New diagnosis of a serious medical condition
- Deterioration of, or failure of treatment for, a medical condition
- Unpleasant, disabling or disfiguring treatment
- Change in medical care, such as discharge from hospital
- Impending death

29.13 Functional somatic syndromes

Medical specialty	Somatic syndromes
Gastroenterology	Irritable bowel syndrome, functional dyspepsia
Gynaecology	Pre-menstrual syndrome, chronic pelvic pain
Rheumatology	Fibromyalgia
Cardiology	Atypical or non-cardiac chest pain
Respiratory medicine	Hyperventilation syndrome
Infectious diseases	Chronic (post-viral) fatigue syndrome
Neurology	Tension headache, non-epileptic attacks, functional gait disorder
Dentistry	Temporomandibular joint dysfunction, atypical facial pain
Ear, nose and throat	Globus syndrome
Allergy medicine	Multiple chemical sensitivity

and depressive disorders. Often these appear understandable as adjustments to illness and its treatment; however, if the anxiety and depression are severe and persistent, they may complicate the management of the medical condition and active management is required. Anxiety may present as an increase in somatic symptoms, such as breathlessness, tremor or palpitations, or as the avoidance of medical treatment. It is most common in those facing difficult or painful treatments, deterioration of their illness or death. Depression may manifest as increased physical symptoms, such as pain, fatigue and disability, as well as with depressed mood and loss of interest and pleasure. It is most common in patients who have suffered actual or anticipated losses, such as receiving a terminal diagnosis or undergoing disfiguring surgery.

Treatment is by psychological and/or pharmacological therapies, as described later in this chapter in the section on depression. Care is required when prescribing psychotropic drugs to the medically ill in order to avoid exacerbation of the medical condition and harmful interactions with other prescribed drugs.

Medically unexplained somatic symptoms

Medically unexplained somatic symptoms (MUS) is the term used to describe the situation where patients have symptoms that cannot be entirely explained on the basis of a physical disorder (see Fig. 29.4). They fall into characteristics patterns (see Box 29.13) and are very common in patients attending general medical outpatient clinics. Almost any symptom can be medically unexplained, including:

- pain (including back, chest, abdominal, pelvic and headache)
- fatigue
- fits, ‘funny turns’, dizziness and feelings of weakness.

Patients with MUS may receive a medical diagnosis of a so-called ‘functional somatic syndrome’, such as irritable bowel syndrome (Box 29.13), and may also merit a psychiatric diagnosis on the basis of the same symptoms. The most frequent psychiatric diagnoses associated with MUS are anxiety or depressive disorders. When these are absent, a diagnosis of bodily distress disorder may be appropriate. Bodily distress disorders are discussed in more detail later in this chapter.

Self-harm

Self-harm (SH) is a common reason for presentation to medical services. The term ‘attempted suicide’ is potentially misleading, as most of these patients are not trying to kill themselves. Most cases of SH involve overdose, of either prescribed or non-prescribed drugs (Ch. 11). Less common methods include asphyxiation, drowning, hanging, jumping from a height or in front of a moving vehicle, and the use of firearms. Methods that carry a high chance of being fatal are more likely to be associated with serious psychiatric disorder. Self-cutting is common and often repetitive, but rarely leads to contact with medical services.

29.14 Risk factors for suicide

- Psychiatric illness (depressive illness, schizophrenia)
- Older age
- Male sex
- Living alone
- Unemployment
- Recent bereavement, divorce or separation
- Chronic physical ill health
- Drug or alcohol misuse
- Suicide note written
- History of previous attempts (especially if a violent method was used)

The incidence of SH varies over time and between countries. In the UK, the lifetime prevalence of suicidal ideation is 15% and that of acts of SH is 4%–5%. SH is more common in women than men, and in young rather than older adults. In contrast, completed suicide is more common in men and older people (Box 29.14). There is a higher incidence of SH among lower socioeconomic groups, particularly those living in crowded, socially deprived urban areas. There is also an association with alcohol misuse, child abuse, unemployment and recent relationship problems.

Clinical assessment

The main differential diagnosis is from accidental poisoning and so-called ‘recreational’ overdose in drug users. It must be remembered that SH is not a diagnosis, but a presentation, and may be associated with any psychiatric diagnosis, the most common being adjustment disorder, substance and alcohol misuse, depressive disorder and personality disorder. In many cases, however, no psychiatric diagnosis can be made.

Management

A thorough psychiatric and social assessment should be attempted in all cases (Fig. 29.1), although some patients will discharge themselves before this can take place. The need for psychiatric assessment should not delay urgent medical or surgical treatment, though, and may need to be deferred until the patient is well enough for interview. The purpose of the psychiatric assessment is to:

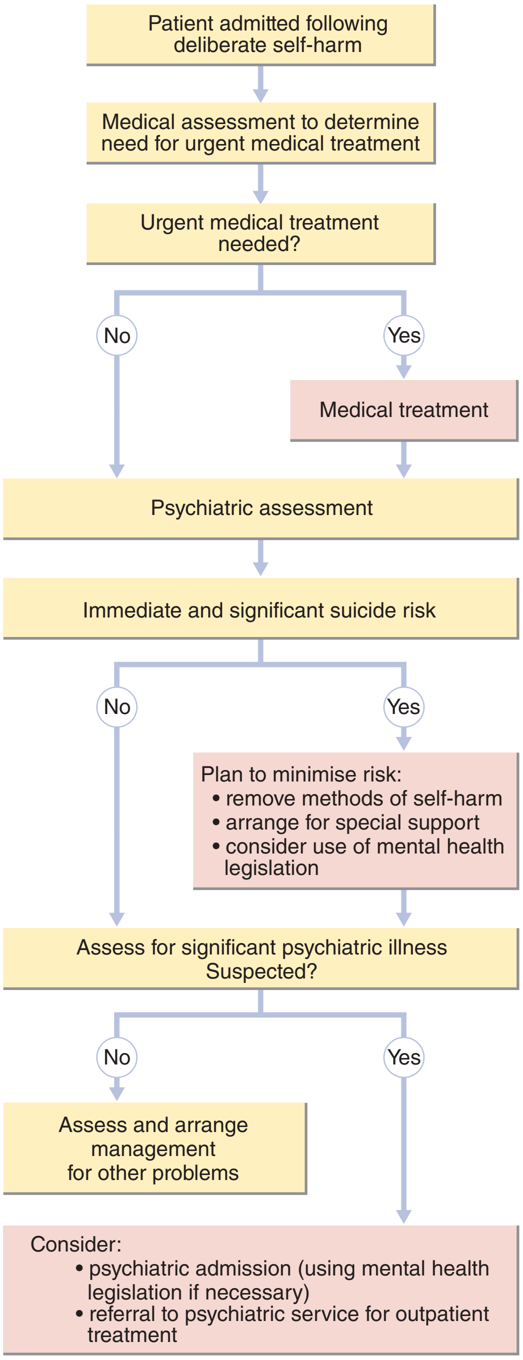
- establish the short-term risk of suicide
- identify potentially treatable problems, whether medical, psychiatric or social.

Topics to be covered when assessing a patient are listed in Box 29.15. The history should include events occurring immediately before and after the act, and especially any evidence of planning. The nature and severity of any current psychiatric symptoms must be assessed, along with the personal and social supports available to the patient outside hospital.

Most SH patients have depressive and anxiety symptoms on a background of chronic social and personal difficulties (often complicated by use of alcohol or other substances), but no psychiatric disorder. They do not usually require psychotropic medication or specialised psychiatric treatment, but may benefit from personal support and practical advice from a GP, social worker or community psychiatric nurse. Admission to a psychiatric ward is necessary only for persons who display one or more of the following:

- an acute psychiatric disorder
- high short-term risk of suicide
- need for temporary respite from intolerable circumstances
- requirement for further assessment of their mental state.

Approximately 20% of SH patients make a repeat act during the following year and 1%–2% kill themselves. Factors associated with suicide after an episode of SH are listed in Box 29.14.



Patient admitted following deliberate self-harm
Medical assessment to determine need for urgent medical treatment
Urgent medical treatment needed?
No
Yes
Medical treatment
Psychiatric assessment
Immediate and significant suicide risk
No
Yes
Plan to minimise risk:
• remove methods of self-harm
• arrange for special support
• consider use of mental health legislation
Assess for significant psychiatric illness
Suspected?
No
Yes
Assess and arrange management for other problems
Consider:
• psychiatric admission (using mental health legislation if necessary)
• referral to psychiatric service for outpatient treatment

Fig. 29.1 **Assessment of patients admitted following self-harm.**

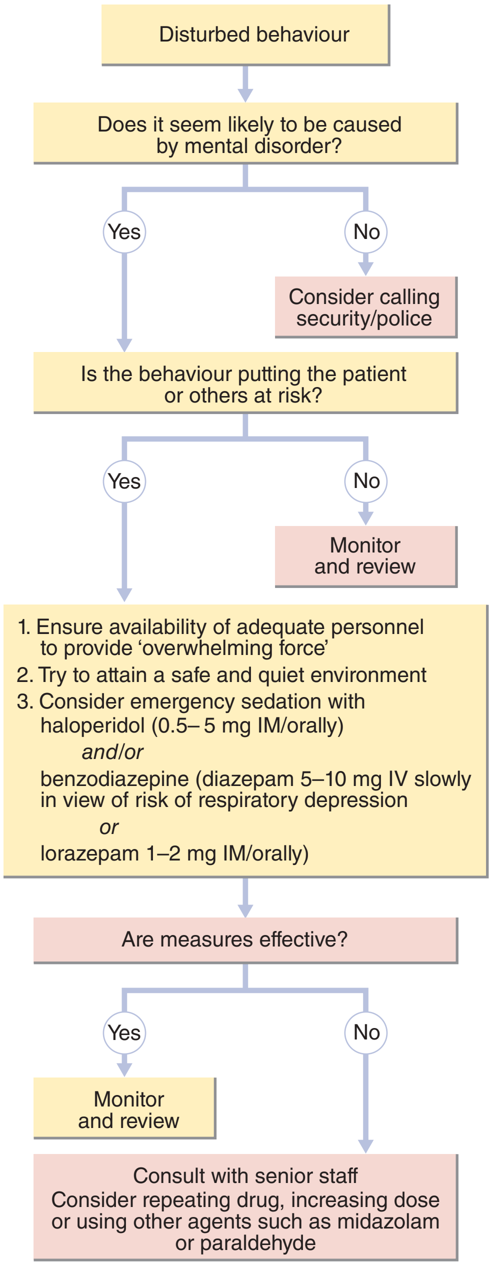
29.15 Assessment of patients after self-harm

Current attempt

- Patient's account
- Degree of intent at the time: preparations, plans, precautions against discovery, note
- Method used, particularly whether violent
- Degree of intent now
- Symptoms of psychiatric illness

Background

- Previous attempts and their outcome
- Family and personal history
- Social support
- Previous response to stress
- Extent of drug and alcohol misuse



Disturbed behaviour
Does it seem likely to be caused by mental disorder?
Yes
No
Consider calling security/police
Is the behaviour putting the patient or others at risk?
Yes
No
Monitor and review
1. Ensure availability of adequate personnel to provide 'overwhelming force'
2. Try to attain a safe and quiet environment
3. Consider emergency sedation with haloperidol (0.5–5 mg IM/orally)
and/or
benzodiazepine (diazepam 5–10 mg IV slowly in view of risk of respiratory depression
or
lorazepam 1–2 mg IM/orally)
Are measures effective?
Yes
No
Monitor and review
Consult with senior staff
Consider repeating drug, increasing dose or using other agents such as midazolam or paraldehyde

Fig. 29.2 **Acute management of disturbed behaviour.** (IM = intramuscular; IV = intravenous)

Disturbed and aggressive behaviour

Disturbed and aggressive behaviour is common in general hospitals, especially in emergency departments. Most behavioural disturbance arises not from medical or psychiatric illness, but from alcohol intoxication, reaction to the situation and personality characteristics.

Clinical assessment

The key principles of management are, firstly, to establish control of the situation rapidly and thereby ensure the safety of the patient and others; and secondly, to try to determine the cause of the disturbance in order to remedy it. Establishing control requires the presence of an adequate number of trained staff, an appropriate physical environment and sometimes sedation (Fig. 29.2). The assistance of hospital security staff and sometimes the police may be required. In all cases, the staff approach

29.16 Psychiatric emergencies

- Intervene as necessary to reduce the risk of harm to the patient and to others
- Adopt a calm, non-threatening approach
- Arrange availability of other staff and parenteral medication
- Consider diagnostic possibilities of drug intoxication, acute psychosis and delirium
- Involve friends and relatives as appropriate

is important; a calm, non-threatening manner expressing understanding of the patient's concerns is often all that is required to defuse potential aggression (Box 29.16).

An attempt should be made to try to identify the factors that are contributing to the disturbed behaviour. When the patient is cooperative, these factors are best determined at interview. Other sources of information about the patient include medical and psychiatric records, and discussion with nursing staff, family members and other informants, including the patient's GP. The following information should be sought:

- psychiatric, medical (especially neurological) and criminal history
- current psychiatric and medical treatment
- alcohol and drug misuse
- recent stressors
- the time course and accompaniments of the current episode in terms of mood, belief and behaviour.

Observation of the patient's behaviour may also yield useful clues. Do they appear to be responding to hallucinations? Are they alert or variably drowsy and confused? Are there physical features suggestive of drug or alcohol misuse or withdrawal? Are there new injuries or old scars, especially on the head? Do they smell of alcohol or solvents? Do they bear the marks of drug injection? Are they unwashed and unkempt, suggesting a gradual development of their condition?

Investigations

Depending on the results of clinical assessment, routine biochemistry, haematology and analysis of blood or urine for illicit drugs or alcohol may be required.

Management

Measures such as restraint and sedation may be required in patients with acute behavioural disturbance, in order to identify the cause and to protect the patient and other people from harm. While this potentially raises legal issues, in most countries, including the UK, common law confers on doctors the right, and indeed the duty, to intervene against a patient's wishes if this is necessary. Sedation may be required and can be achieved with antipsychotic drugs (such as haloperidol) and/or benzodiazepines (such as lorazepam or diazepam). The choice of drug, dose, route and rate of administration depends on the patient's age, gender and physical health, as well as the likely cause of the disturbed behaviour. The benefits of sedation must always be balanced against the potential risks. When prescribing benzodiazepines, consider the risk of respiratory depression (particularly in patients with lung disease) and encephalopathy (in those with liver disease). When prescribing antipsychotic drugs for acute sedation, consider the risk of acute dystonias (such as 'oculogyric crisis') and acute arrhythmias (in patients with heart disease). Thus, for a frail older woman with emphysema and delirium, sedation may be achieved with a low dose (0.5 mg) of oral haloperidol, while for a strong young man with an acute psychotic episode, 10 mg or more of intravenous diazepam and a similar dose of haloperidol may be required. A parenterally administered anticholinergic agent, such as procyclidine, should be available to treat extrapyramidal effects from haloperidol if they arise. Flumazenil can be used to reverse respiratory depression caused by benzodiazepines.

If the initial assessment suggests that the patient has an acute psychiatric disorder, then admission to a psychiatric facility may be indicated. If a medical cause is more likely, psychiatric transfer is usually inappropriate and the patient should be managed in a medical setting, with whatever nursing and security support is required. Where it is clear that there is no medical or psychiatric illness, the person should be removed from the hospital, to police custody if necessary.

Many countries, such as the UK, also have specific mental health legislation that may be used to detain patients if necessary.

Principles of management

The multifactorial origin of most psychiatric disorders means that there are multiple potential targets for treatment. It is useful to consider management strategies within a bio-psycho-social framework. This can help to address the biological factors that contribute to the illness with medication and other physical treatments such as electroconvulsive therapy, while also considering the potential role for psychological therapies and changes to the patient's social environment.

Pharmacological treatments

These aim to relieve psychiatric disorder by modifying brain function. The main biological treatments are psychotropic drugs. These are widely used for various purposes; a pragmatic classification is set out in Box 29.17. It should be noted that some drugs have applications to more than one condition; for example, antidepressants are also widely used in the treatment of anxiety and chronic pain. The specific subgroups of psychotropic drugs are discussed in the sections on the appropriate disorders below.

29.17 Classification of commonly used psychotropic drugs

Action	Main groups	Clinical use
Antipsychotic	Phenothiazines Butyrophenones Second-generation antipsychotics	Schizophrenia Bipolar mania Delirium
Antidepressant	Tricyclics and related drugs Serotonin and noradrenergic re-uptake inhibitors Monoamine oxidase inhibitors Esketamine	Depression/anxiety Obsessive–compulsive disorder Depression/anxiety Adjunctive therapy in treatment of resistant depression
Mood-stabilising	Lithium Sodium valproate Lamotrigine	Treatment and prophylaxis of bipolar disorder Adjunctive therapy in bipolar disorder
Anti-anxiety	Benzodiazepines β-adrenoceptor antagonists (β-blockers)	Anxiety/insomnia (short term) Alcohol withdrawal (short term) Anxiety (somatic symptoms)

Electroconvulsive therapy

Electroconvulsive therapy (ECT) entails producing a convulsion by the brief administration of a high-voltage direct-current impulse to the head while the patient is anaesthetised and paralysed by muscle relaxant. If properly administered, it is remarkably safe, has few side-effects and is of proven efficacy for severe depressive illness. There may be headaches and amnesia for events occurring a few hours before ECT (retrograde) and after it (anterograde). Pronounced amnesia can occur, but is infrequent and difficult to distinguish from the effects of severe depression.

Other forms of electromagnetic stimulation

Clinical trials of transcranial magnetic stimulation (TMS) and vagal nerve stimulation (VNS) suggest they may have a limited role in patients with depression refractory to conventional treatments.

Surgery

Surgery to the brain (psychosurgery) has a very limited place and then only in the treatment of severe chronic psychiatric illness resistant to other measures. Frontal lobotomies are never done now, and pre-frontal leucotomies are very rare. Operations these days usually target specific subregions and tracts of the brain.

Psychological therapies

These treatments are useful in many psychiatric disorders and also in non-psychiatric conditions. They are based on talking with patients, either individually or in groups. Sometimes discussion is supplemented by ‘homework’ or tasks to complete between treatment sessions. Psychological treatments take a number of forms based on the duration and frequency of contact, the specific techniques applied and their underlying theory.

General supportive psychotherapy

General psychotherapy should be part of all medical treatment. It involves empathic listening to the patient’s account of their symptoms and associated fears and concerns, followed by the sympathetic provision of accurate information that addresses these.

Cognitive therapy

This therapy is based on the observation that some psychiatric disorders are associated with systematic errors in the patient’s conscious thinking, such as a tendency to interpret events in a negative way or see them as unduly threatening. A triad of ‘cognitive errors’ has been described in depression (Box 29.18). Cognitive therapy aims to help patients to identify such cognitive errors and to learn how to challenge them. It is widely used for depression, anxiety, and eating and bodily distress disorders, and also increasingly in psychoses.

Behaviour therapy

This is a practically orientated form of treatment, in which patients are assisted in changing unhelpful behaviour, such as helping patients to implement carefully graded exposure to the feared stimulus in phobias.

29.18 The negative cognitive triad associated with depression

Cognitive error	Example
Negative view of self	‘I am no good’
Negative view of current life experiences	‘The world is an awful place’
Negative view of the future	‘The future is hopeless’

29.19 Stages of problem-solving therapy

- Define and list problems
- Choose one to work on
- List possible solutions
- Evaluate these and choose the best
- Try it out
- Evaluate the result
- Repeat until problems are resolved

Cognitive behaviour therapy

Cognitive behaviour therapy (CBT) combines the methods of behaviour therapy and cognitive therapy. It is the most widely available and extensively researched psychological treatment.

Problem-solving therapy

This is a simplified brief form of CBT, which helps patients actively tackle problems in a structured way (Box 29.19). It can be delivered by non-psychiatric doctors and nurses after appropriate training and is commonly used to help patients who self-harm in response to a situational crisis.

Psychodynamic psychotherapy

This treatment, also known as ‘interpretive psychotherapy’, was pioneered by Freud, Jung and Klein, among others. It is based on the theory that early life experience generates powerful but unconscious motivations. Psychotherapy aims to help the patient to become aware of these unconscious factors on the assumption that, once identified, their negative effects are reduced. The relationship between therapist and patient is used as a therapeutic tool to identify issues in patients’ relationships with others, particularly parents, which may be replicated or transferred to their relationship with the therapist. Explicit discussion of this relationship is the basis for the treatment, which traditionally requires frequent sessions over a period of months or even years.

Interpersonal psychotherapy

Interpersonal psychotherapy (IPT) is a specific form of brief psychotherapy that focuses on patients’ current interpersonal relationships and is an effective treatment for mild to moderate depression.

Social interventions

Some adverse social factors, such as unemployment, may not be readily amenable to intervention, but others, such as access to benefits and poor housing, may be. Patients can be helped to address these problems themselves by being taught problem-solving. Befrienders and day centres can reduce social isolation, benefits advisers can ensure appropriate financial assistance, and medical recommendations can be made to local housing departments to help patients obtain more appropriate accommodation.

Psychiatric disorders

Neurodevelopmental disorders

Neurodevelopmental disorders are emerging as a critical public health problem, given their prevalence, increased recognition and lifelong effects on individuals and society. The global prevalence of autism (~1%), attention deficit/hyperactivity disorder (~2%, 5%–10% of young boys), and specific learning disorders (15%–20% overall and as many as 1 in 3 schoolchildren) mean that most school classes of 20–30 will include a substantial minority with one or more conditions. General learning disability (LD, known as intellectual disability in the USA) is by definition an IQ of less than 70 and is found in 2.5% of the population. Comorbidity is common. Neurodevelopmental disorders are more common in males, with the exception of autism, which has an equal sex prevalence.

Most neurodevelopmental conditions are highly heritable, and up to 50% have a detectable genetic anomaly. Copy number variations (CNVs), an extra copy or deletion of genes, such as 22q11.2 deletion (DiGeorge or velocardiofacial syndrome) are common causes (found, for example, in ~11% of adults accessing LD services in the UK) and are associated with congenital physical anomalies, epilepsy and an increased risk of physical and mental illness in adulthood. Other known risk factors include advanced parental age, obstetric complications and in utero exposure to antiepileptics, such as carbamazepine and especially valproate. Contrary to the views of some comentators, there is no relationship with vaccinations.

Autism

Classical infantile regressive autism, as originally described by Kanner, where infants lose previously acquired social and other skills, is rare. Syndromic autism, where an autism spectrum disorder (ASD) is part of a broader medical condition, affects about 25% of cases. Specific gene abnormalities are increasingly recognised. Rett syndrome is caused by a pathogenic variant in the *MECP2* gene, and given the typical early death is a possible target for gene therapy. Fragile X is a non-Mendelian trinucleotide repeat disorder involving the *FMR1* gene, which is the most common monogenic cause of autism; relatives with fewer trinucleotide repeats can demonstrate a milder phenotype, including cognitive impairment.

Non-syndromic or idiopathic autism has typically polygenic inheritance. Various combinations of milder difficulties in communication and social interaction, and a restricted pattern of behaviour and interests are characteristic. They tend to become problematic on changing educational establishments or the demands of relationships and jobs. Intensive behavioural and parent-mediated interventions in early childhood are likely to help, but there are no specific drug treatments. Management is, therefore, generally aimed at trying to support individuals and carers, and educational or occupational adaptations including, for example, clear communication and expectations.

Attention deficit/hyperactivity disorder

Low family income and being young for one's school year increase the risk of being diagnosed with attention deficit/hyperactivity disorder (ADHD). Untreated ADHD can severely disrupt education and set young males on a path to exclusion, conduct disorder, psychopathy, substance use and crime. Adult-onset cases are, however, increasingly recognised. Parenting classes, to provide strategies such as clear boundaries and praise rather than criticism and punishment, can help. Treatment with stimulants is highly effective, with an effect size of around 1, making it one of the most potent interventions in all of medicine and around 1% of young people would likely benefit. Long-term treatment can, however, limit growth and raise cardiovascular risk and so drug holidays (e.g. in the summer) can be helpful.

Specific learning disorders

Relatively constrained problems with reading (dyslexia), writing (dysgraphia), arithmetic (dyscalculia) and coordination (dyspraxia) are now much more accepted as 'real', rather than evidence of 'stupidity' as they were in previous times. Indeed, they have relatively discrete neuroimaging correlates and such difficulties can arise, for example, after stroke. Educational support and adjustments can help. As with many neurodevelopmental disorders, difficulties can ease as people get older, both because of neurobiological maturation and learning 'get-arounds'.

Neurodiversity

Neurodiversity was originally a framework from the disability rights movement, applied first to those with high-functioning autism. It built on the social model that disability partly arises from social barriers rather than just biological deficits. It situates human cognitive variation in the context of biodiversity and the politics of minority groups. Some of those affected adopt the label 'neurodiverse' and request environmental adjustments and accommodation of individual differences in, for example, interventions for other mental health problems. Regardless of the politics, neurodivergent people, including those with autism, ADHD and dyslexia, often possess additional abilities in deep focus, lateral thinking and innovation, which can be an asset in the information technology and creative industries.

Schizophrenia

Schizophrenia is characterised by delusions, hallucinations and lack of insight. Acute schizophrenia may also present with disturbed behaviour, disordered thinking, or with insidious social withdrawal and other so-called negative symptoms and less obvious delusions and hallucinations. Schizophrenia occurs worldwide in all ethnic groups with a prevalence of about 0.5%. It is more common in men (1.4 to 1). Children of an affected parent have an approximate 10% risk of developing the illness, but this rises to 50% if an identical twin is affected. The usual age of onset is the mid-twenties but can be older, particularly in women.

Pathogenesis

There is a strong genetic contribution, usually involving many susceptibility genes, each of small effect, but 2%–3% of cases can be attributed to increased or decreased copies of genes (CNVs). Environmental risk factors include a history of obstetric complications at the time of the patient's birth, childhood adversity and urban upbringing. Brain imaging techniques have identified subtle structural abnormalities in groups of people with schizophrenia, including an overall decrease in brain size (by about 3% on average), with a relatively greater reduction in temporal lobe volume (5%–10%). Episodes of acute schizophrenia may be precipitated by social stress and also by cannabis, which increases dopamine turnover. Consequently, schizophrenia is now viewed as a neurodevelopmental disorder, caused by abnormalities of brain development associated with genetic predisposition and early environmental influences, but precipitated by later triggers.

Clinical features

Acute schizophrenia should be suspected in any individual with bizarre behaviour accompanied by delusions and hallucinations that are not due to organic brain disease or substance misuse. The characteristic clinical features are listed in Box 29.20. Hallucinations are typically auditory, but can occur in any sensory modality. They commonly involve voices from outside the head that talk to or about the person. Sometimes the voices repeat the person's thoughts. Patients may also describe 'passivity of

29.20 Symptoms of schizophrenia

First-rank symptoms of acute schizophrenia

- A = Auditory hallucinations – second- or third-person/écho de la pensée
- B = Broadcasting, insertion/withdrawal of thoughts
- C = Controlled feelings, impulses or acts ('passivity' experiences/phenomena)
- D = Delusional perception (a particular experience is bizarrely interpreted)

Symptoms of chronic schizophrenia (negative symptoms)

- Flattened (blunted) affect
- Apathy and loss of drive (avolition)
- Social isolation/withdrawal (autism)
- Poverty of speech (alogia)
- Poor self-care

thought', experienced as disturbances in the normal privacy of thinking, such as the delusional belief that their thoughts are being 'withdrawn' from them and perhaps 'broadcast' to others, and/or that alien thoughts are being 'inserted' into their mind. Other characteristic symptoms are delusions of control: believing that one's emotions, impulses or acts are controlled by others. Another phenomenon is delusional perception, a delusion that arises suddenly alongside a normal perception, such as 'I saw the moon and I immediately knew he was evil'. Other, less common, symptoms may occur, including thought disorder, as manifest by incomprehensible speech, and abnormalities of movement, such as those in which the patient can become immobile or adopt awkward postures for prolonged periods (catatonia).

Diagnosis

The diagnosis is made primarily on clinical grounds, but investigations may be required to rule out organic brain disease. The main differential diagnosis of schizophrenia (Box 29.21) includes:

- *Other functional psychoses*, particularly psychotic depression and mania, in which delusions and hallucinations are congruent with a marked mood disturbance (negative in depression and grandiose in mania). Schizophrenia must also be differentiated from specific delusional disorders that are not associated with the other typical features of schizophrenia.
- *Organic psychoses*, including delirium, in which there is impairment of consciousness and loss of orientation (not found in schizophrenia), typically with visual hallucinations.
- *Drug misuse*, particularly in young people.
- *Autoimmune or infectious encephalitis*.
- *Temporal lobe epilepsy*, with psychotic symptoms, in which olfactory and gustatory hallucinations may occur.

Many of those who experience acute schizophrenia go on to develop a chronic state in which the acute, so-called positive symptoms resolve, or at least do not dominate the clinical picture, leaving so-called negative symptoms that include blunt affect, apathy, social isolation, poverty of speech and poor self-care. Patients with chronic schizophrenia may also manifest positive symptoms, particularly when under stress, and it can be difficult for those who do not know the patient to judge whether or not these are signs of an acute relapse.

29.21 Differential diagnosis of schizophrenia

Alternative diagnosis	Distinguishing features
Other functional psychoses	
Delusional disorders	Absence of specific features of schizophrenia
Psychotic depression	Prominent depressive symptoms
Manic episode	Prominent manic symptoms
Schizoaffective disorder	Mood and schizophrenia symptoms both prominent
Puerperal psychosis	Acute onset after childbirth
Organic disorders	
Drug-induced psychosis	Evidence of drug or alcohol misuse
Side-effects of prescribed drugs	Levodopa, methyldopa, glucocorticoids, antimalarial drugs
Temporal lobe epilepsy	Other evidence of seizures
Delirium	Visual hallucinations, impaired consciousness
Dementia	Age, established cognitive impairment
Huntington disease	Family history, choreiform movements, dementia

Investigations

As in dementia, investigations are focused on excluding a treatable cause, such as a slow-growing brain tumour, temporal lobe epilepsy, neurosyphilis or various autoimmune conditions. These are required only in patients with neurological or other organic symptoms or signs.

Management

First-episode schizophrenia often requires admission to hospital because patients lack the insight that they are ill and are unwilling to accept treatment. In some cases, they may be at risk of harming themselves or others. Subsequent acute relapses and chronic schizophrenia are now usually managed in the community.

Drug treatment

Antipsychotic agents are effective against the positive symptoms of schizophrenia in the majority of cases. They take 2 weeks or so to be maximally effective, but have some beneficial effects shortly after administration. Treatment is then ideally continued to prevent relapse. In a patient with a first episode of schizophrenia this will usually be for 1 or 2 years, but in patients with multiple episodes, treatment may be required for many years. The benefits of prolonged treatment must be weighed against the adverse effects, which include extrapyramidal side-effects (EPSE) like acute dystonic reactions (which may require treatment with parenteral anticholinergics), akathisia and parkinsonism. For long-term use, antipsychotic agents are often given by slow-release (depot) injections to improve adherence.

A number of antipsychotic agents are available (Box 29.22). These may be divided into first-generation drugs such as chlorpromazine and haloperidol, and second-generation drugs such as olanzapine and clozapine. In general, the newer drugs are less likely to produce unwanted EPSE, but tend to cause greater weight gain and metabolic disturbances, such as dyslipidaemia. All work by blocking D_2 dopamine receptors in the brain, with the possible exception of clozapine. Clozapine can be remarkably effective in those who do not respond to other antipsychotics, but can cause agranulocytosis in about 1% of patients in the first few months. Prescription therefore requires regular monitoring of white blood cell count, initially on a weekly basis, then fortnightly and monthly thereafter. Clozapine, like all antipsychotics, should not be stopped suddenly because of the likelihood of relapse. Adverse effects of antipsychotic drugs are listed in Box 29.23. Two serious adverse effects deserve special mention.

Neuroleptic malignant syndrome This is a rare but serious condition characterised by fever, tremor and rigidity, autonomic instability and delirium. Characteristic laboratory findings are an elevated creatinine phosphokinase and leucocytosis. Antipsychotic medication must be stopped immediately and supportive therapy provided, often in an intensive care unit. Treatment includes ensuring hydration and reducing hyperthermia.

29.22 Antipsychotic drugs

Group	Drug	Usual adult dose*
Phenothiazines	Chlorpromazine	400–600 mg daily
Butyrophenones	Haloperidol	8–12 mg daily
Thioxanthenes	Flupentixol decanoate	40 mg fortnightly (depot injection)
Diphenylbutylpiperidines	Pimozide	8–10 mg daily
Substituted benzamides	Sulpiride	800–1200 mg daily
Dibenzodiazepines[2]	Clozapine	300–600 mg daily
Benzisoxazole[2]	Risperidone	4–6 mg daily
Thienobenzodiazepines[2]	Olanzapine	10–15 mg daily
Dibenzothiazepines[2]	Quetiapine	300–600 mg daily

*Lower or higher doses may be required in some patients. [2]Second-generation antipsychotics.

i 29.23 Adverse effects of antipsychotic drugs

Weight gain due to increased appetite

Effects due to dopamine blockade*

- Acute dystonia
- Akathisia (motor restlessness)
- Parkinsonism
- Tardive dyskinesia
- Gynaecomastia
- Galactorrhoea

Effects due to cholinergic blockade

- Dry mouth
- Blurred vision
- Impotence
- Constipation
- Urinary retention

Hypersensitivity reactions

- Blood dyscrasias (neutropenia with clozapine)
- Cholestatic jaundice
- Photosensitive dermatitis

Ocular complications

- Corneal and lens opacities (long-term use)

*Less severe with clozapine, quetiapine and olanzapine, possibly because of strong 5-hydroxytryptamine-blocking effect and relatively weak dopamine blockade.

Dantrolene sodium and bromocriptine may be helpful. Mortality is 20% untreated and 5% with treatment.

Cardiac arrhythmias Antipsychotic medications cause prolongation of the QTc interval, which may be associated with ventricular tachycardia, torsades de pointes and sudden death. If this occurs, treatment should be reviewed, with careful electrocardiographic monitoring and treatment of serious arrhythmias if necessary.

Psychological treatment

Psychological treatment, including general support for the patient and family, is now seen as an essential component of management. CBT may help patients to cope with symptoms. There is evidence that personal and/or family education, when given as part of an integrated treatment package, reduces the rate of relapse.

Social treatment

After an acute episode of schizophrenia has been controlled by drug therapy, social rehabilitation may be required. Recurrent illness is likely to cause disruption to patients' relationships and their ability to manage their accommodation and occupation; consequently, patients with schizophrenia often need help to obtain housing and employment. A graded return to employment and sometimes a period of supported accommodation may be required.

Patients with chronic schizophrenia have particular difficulties and may need long-term, supervised accommodation. This now tends to be in supported accommodation in the community. Patients may also benefit from sheltered employment if they are unable to participate effectively in the labour market. Ongoing contact with a health worker allows monitoring for signs of relapse, sometimes as part of a multidisciplinary team working to agreed plans (the 'care programme approach'). Partly because of a tendency to inactivity, smoking and a poor diet, patients with chronic schizophrenia are at increased risk of cardiovascular disease, diabetes and stroke, and require proactive medical as well as psychiatric care.

Prognosis

About one-third of those who develop an acute schizophrenic episode have a good outcome. One-third develop chronic, incapacitating schizophrenia, and the remainder largely recover after each episode but suffer relapses. Most affected patients cannot work or live independently. Schizophrenia is associated with suicide and up to 10% of patients take their own lives.

Mood disorders

Mood or affective disorders include:

- *unipolar depression*: one or more episodes of low mood and associated symptoms
- *bipolar disorder*: episodes of elevated mood interspersed with episodes of depression
- *dysthymia*: chronic low-grade depressed mood without sufficient other symptoms to count as 'clinically significant' or 'major' depression.

Depression

Major depressive disorder has a prevalence of 5% in the general population and approximately 10%–20% in chronically ill medical outpatients, including older adults (see Box 29.6). It is a major cause of disability and suicide. If comorbid with a medical condition, depression magnifies disability, diminishes adherence to medical treatment and rehabilitation, and may even shorten life expectancy.

Pathogenesis

There is a genetic predisposition to depression, especially when of early onset. The genetic predisposition is mediated by variants in a large number of genes of small effect rather than pathological variations in single genes. Adversity and abuse early in life also predispose to depression. Depressive episodes are often, but not always, triggered by stressful life events (especially those that involve loss or imposed change), including medical illnesses. Associated biological factors include hypofunction of monoamine neurotransmitter systems, including 5-HT and noradrenaline (norepinephrine), and abnormalities of the hypothalamic–pituitary–adrenal (HPA) axis, which results in elevated cortisol levels that do not suppress with dexamethasone.

Diagnosis

The symptoms are listed in Box 29.8. Depression may be mild, moderate or severe. It may also be recurrent or chronic. It can be both a complication of a medical condition and a cause of MUS (see below), so physical examination is essential; an associated medical condition should always be considered, particularly where there is no past history of depression and no apparent psychological precipitant.

Investigations

Investigations are not usually required unless there are clinical grounds for suspicion of an underlying medical disorder, such as Cushing syndrome or hypothyroidism.

Management

Pharmacological and psychological treatments both work in depression. In practice, the choice is determined by patient preference and local availability. Severe depression complicated by psychotic symptoms, dehydration or suicide risk may require ECT.

Drug treatment

Antidepressant drugs are effective in moderate and severe depression, whether it is primary or secondary to a medical illness. The most suitable drug for an individual patient will depend on their previous response, likely side-effects, their concurrent illnesses and potential drug interactions. Commonly used antidepressants are shown in Box 29.24.

The different classes of antidepressant have similar efficacy and about three-quarters of patients respond to treatment. Successful treatment requires the patient to take an appropriate dose of an effective drug for an adequate period. For those who do not respond, a proportion will do so if changed to another class of antidepressant. The patient's progress must be monitored and, after recovery, treatment should be continued for at least 6–12 months to reduce the high risk of relapse. The dose should then be tapered off over several weeks to avoid discontinuation symptoms.

29.24 Antidepressant drugs

Group	Drug	Usual adult dose*
Tricyclic antidepressants	Amitriptyline	75–150 mg daily
	Imipramine	75–150 mg daily
	Dosulepin	75–150 mg daily
	Clomipramine	75–150 mg daily
Selective serotonin re-uptake inhibitors (SSRIs)	Citalopram	20–40 mg daily
	Escitalopram	10–20 mg daily
	Fluoxetine	20–60 mg daily
	Sertraline	50–200 mg daily
	Paroxetine	20–50 mg daily
Monoamine oxidase inhibitors	Phenelzine	45–90 mg daily
	Tranylcypromine	20–40 mg daily
	Moclobemide	300–600 mg daily
Noradrenaline (norepinephrine) re-uptake inhibitors and SSRIs	Venlafaxine	75–375 mg daily
	Duloxetine	60–120 mg daily
Noradrenaline and specific serotonergic inhibitor	Mirtazapine	15–45 mg daily
N-methyl-D-aspartate antagonists	Esketamine	28 mg initially, then 28–84 mg twice weekly, then weekly, then every 1–2 weeks

*Higher doses may be required in some patients: see guidelines. With the exception of esketamine, which is given intranasally, other drugs are given orally.

Tricyclic antidepressants Tricyclic antidepressant (TCA) agents inhibit re-uptake of the amines noradrenaline (norepinephrine) and 5-HT at synaptic clefts. The therapeutic effect is noticeable within a week or two. Adverse effects, such as sedation, anticholinergic effects, postural hypotension, lowering of the seizure threshold and cardiotoxicity, can be troublesome during this period. TCAs may be dangerous in overdose and should be used with caution in people who have coexisting heart disease, glaucoma and prostatism.

Selective serotonin re-uptake inhibitors Selective serotonin re-uptake inhibitors (SSRIs) are less cardiotoxic and less sedative than TCAs, and have fewer anticholinergic effects. They are safer in overdose, but can still cause QTc prolongation, headache, nausea, anorexia and sexual dysfunction. They can also interact with other drugs increasing serotonin (5-HT), to produce ‘serotonin syndrome’. This is a rare syndrome of neuromuscular hyperactivity, autonomic hyperactivity and agitation, and potentially seizures, hyperthermia, delirium and even death.

Noradrenaline (norepinephrine) re-uptake inhibitors These agents primarily inhibit noradrenaline uptake at the synaptic cleft, but have additional pharmacological effects. Venlafaxine and duloxetine also act as serotonin re-uptake inhibitors, whereas mirtazapine also acts as an antagonist at 5-HT2a, 5-HT2c and 5-HT3 receptors. These drugs have similar efficacy to the agents listed above but a different adverse-effect profile.

Monoamine oxidase inhibitors Monoamine oxidase inhibitors (MAOIs) increase the availability of neurotransmitters at synaptic clefts by inhibiting metabolism of noradrenaline (norepinephrine) and 5-HT. They are now rarely prescribed in the UK, since they can cause potentially dangerous interactions with drugs such as amphetamines and certain anaesthetic agents, and with foods rich in tyramine (such as cheese and red wine). This is due to accumulation of amines in the systemic circulation, causing a potentially fatal hypertensive crisis.

Esketamine Esketamine is licensed for treatment-resistant major depressive disorder. It acts as an antagonist at *N*-methyl-D-aspartate (NMDA) receptors and is typically used in patients who have not responded to at least two different treatments.

ECT and related treatments

Electroconvulsive therapy (ECT) is a highly effective and relatively safe treatment for severe depression but, while valuable in the acute setting, its use as a maintenance treatment presents challenges. Transcranial magnetic stimulation (TMS) and the related vagal nerve stimulation (VNS) have shown promise in clinical trials, but are not in widespread clinical use.

Psychological treatment

Both CBT and interpersonal therapy are as effective as antidepressants for mild to moderate depression. Antidepressant drugs are, however, preferred for severe depression. Drug and psychological treatments are more effective in combination.

Prognosis

Over 50% of people who have had one depressive episode and over 90% of people who have had three or more episodes will have another. The risk of suicide in an individual who has had a depressive disorder is 10 times greater than in the general population.

Bipolar disorder

Bipolar disorder is an episodic disturbance with interspersed periods of depressed and elevated mood; the latter is known as hypomania when mild or short-lived, or mania when severe or chronic. The lifetime risk of developing bipolar disorder is approximately 1%–2%. Onset is usually in the twenties, and men and women are equally affected.

Pathogenesis

Bipolar disorder is strongly heritable (approximately 70%). Relatives of patients have an increased incidence of both bipolar and unipolar affective disorder. More than a hundred genetic variants of small effect have been identified by genome-wide association studies. Life events, such as physical illness, sleep deprivation and some medications, such as glucocorticoids, may also play a role in triggering episodes.

Diagnosis

The diagnosis is based on clear evidence of episodes of depression and mania. Isolated episodes of hypomania or mania do occur, but they are usually preceded or followed by an episode of depression. Psychotic symptoms may occur in both the depressive and the manic phases, with delusions and hallucinations that are usually in keeping with the mood disturbance. This is described as an affective psychosis. Patients who present with symptoms of both bipolar disorder and schizophrenia in equal measure may be given a diagnosis of schizoaffective disorder.

Management

Depression should be treated as described above. If antidepressants are prescribed, however, they should be combined with a mood-stabilising drug (see below) to avoid ‘switching’ the patients into (hypo)mania. Manic episodes and psychotic symptoms usually respond well to antipsychotic drugs (see Box 29.22).

Prophylaxis to prevent recurrent episodes of depression and mania with mood-stabilising agents is important. The main drugs used are lithium and sodium valproate, but lamotrigine, olanzapine, quetiapine and risperidone are increasingly employed. Caution must be exercised when stopping these drugs, as a relapse may follow.

Lithiu1m carbonate is the drug of first choice. It is also used for acute mania, and in combination with a tricyclic antidepressant as an adjuvant treatment for resistant depression. It has a narrow therapeutic range, so regular blood monitoring is required to maintain a serum level of 0.5–1.0 mmol/L. Toxic effects include nausea, vomiting, a coarse tremor and convulsions. With long-term treatment, weight gain, hypothyroidism, hyperparathyroidism, arginine vasopressin resistance (formerly known as nephrogenic diabetes insipidus) and chronic renal impairment can occur. Thyroid and renal function should be checked before treatment is started and regularly thereafter. Lithium may be teratogenic and should not be prescribed during the first trimester of pregnancy.

Anticonvulsants, such as sodium valproate and lamotrigine, and some antipsychotic drugs can all be used as prophylaxis in bipolar disorder, usually as a second-line alternative to lithium. Valproate conveys a high risk of birth defects and should not be used in women of child-bearing age. Olanzapine can cause significant weight gain. For a list of the adverse effects of antipsychotic drugs see Box 29.23.

Prognosis

The relapse rate of bipolar disorder is high, although patients may be perfectly well between episodes. After one episode, the annual average risk of relapse is about 10%–15%, which doubles after more than three episodes. There is a substantially increased lifetime risk of suicide of 5%–10%.

Anxiety disorders

These are characterised by the emotion of anxiety, worrisome thoughts, avoidance behaviours and the somatic symptoms of autonomic arousal. Anxiety disorders are divided into three main subtypes: phobic, paroxysmal (panic) and generalised (Box 29.25). The nature and prominence of the somatic symptoms often lead the patient to present initially to medical services. Anxiety may be stress-related and phobic anxiety may follow an unpleasant incident. Many patients with anxiety also have depression.

Clinical features

Phobic anxiety disorder

A phobia is an abnormal or excessive fear of a specific object or situation, which leads to avoidance of it (such as excessive fear of dying in an air crash, leading to avoidance of flying). A general phobia of going out alone or being in crowded places is called ‘agoraphobia’. Phobic responses can develop to medical procedures such as venepuncture.

Panic disorder

Panic disorder describes repeated attacks of severe anxiety, which are not restricted to any particular situation or circumstances. Somatic symptoms, such as chest pain, palpitations and paraesthesia in lips and fingers, are common. The symptoms are in part due to involuntary over-breathing (hyperventilation). Patients with panic attacks often fear that they are suffering from a serious illness, such as a heart attack or stroke, and seek emergency medical attention. Panic disorder may coexist with agoraphobia.

Generalised anxiety disorder

This is typically a recurrent or a chronic anxiety state associated with uncontrollable worry. The associated muscle tension often leads to a variety of medical presentations.

Diagnosis

The diagnosis is made on the basis of clinical history and typical symptoms, as described above. Where a diagnosis of panic disorder is suspected, it can be confirmed by asking the patient to hyperventilate deliberately for 1–2 minutes and observing whether the symptoms are reproduced. A finding of respiratory alkalosis on arterial blood gas measurement is indicative of chronic hyperventilation.

29.25 Classification of anxiety disorders

	Phobic anxiety disorder	Panic disorder	Generalised anxiety disorder
Occurrence	Situational	Paroxysmal	Persistent
Behaviour	Avoidance	Escape	Agitation
Cognitions	Fear of situation	Fear of symptoms	Worry
Symptoms	On exposure	Episodic	Persistent

Management

Psychological treatment

Explanation and reassurance are essential, especially when patients fear they have a serious medical condition. Specific treatment may be needed. Treatments include relaxation, graded exposure (desensitisation) to feared situations for phobic disorders, and CBT.

Drug treatment

Antidepressants are the drugs of first choice. The therapeutic dose can be higher – and response delayed – for anxiety disorders than for depression and there is some evidence that, within their respective classes, escitalopram (SSRI), duloxetine (SNRI) and clomipramine (TCA) have greatest efficacy against anxiety disorders. Activating side-effects of some antidepressants can lead to a worsening of anxiety symptoms in the first 2 weeks, and patients should be warned of this.

Benzodiazepines are useful in the short-term, but regular long-term use carries a high risk of dependence. Regular prescriptions should, therefore, be limited to 3 weeks; beyond that, prescriptions should be restricted to occasional use as required, with periodic review to guard against dose escalation. Short-acting benzodiazepines, such as lorazepam, have a rapid onset and provide symptomatic relief for up to 2 hours but have the greatest potential for dependence. Longer-acting drugs, such as diazepam, can take an hour to take effect when given orally but provide symptomatic relief for up to 12 hours. The gamma-aminobutyric acid (GABA) analogue pregabalin is an effective alternative but can also lead to tolerance and dependence. A β-adrenoceptor antagonist (β-blocker), such as propranolol, can help when somatic symptoms are prominent.

Obsessive–compulsive disorder

Obsessive–compulsive disorder (OCD) is characterised by ‘obsessions’ – thoughts, images or impulses that are recurrent, unwanted and usually anxiety-provoking, but recognised as one’s own. In many cases, the obsessions give rise to ‘compulsions’, which are repeated acts performed to relieve the anxiety. Unlike the anxiety disorders discussed above, which are more common in women, OCD is equally common in men and women.

Clinical features

Common examples include fears of contamination, giving rise to repeated and ritualised hand-washing, and concerns about having forgotten something, giving rise to time-consuming repeated checking. The differential diagnoses include normal checking behaviour and delusional beliefs about thought possession.

Diagnosis

The diagnosis is made on the basis of the typical history, as described above.

Management

Obsessive–compulsive disorder usually responds to some degree to antidepressant drugs (high-dose clomipramine or SSRI; see Box 29.24) and to ‘exposure response prevention’ – a form of CBT in which patients are encouraged to expose themselves to the feared thought or situation without performing the anxiety-relieving compulsions. Relapses are common, however, and the condition often becomes chronic.

Stress-related disorders

Acute stress reaction

Following a traumatic or life-threatening event, such as an assault or a major accident, some people develop a characteristic pattern of symptoms: an initial state of ‘daze’ or bewilderment is followed by altered activity (withdrawal or agitation), often with anxiety. The symptoms are transient and usually resolve completely within a few days. The lay media often describes this as 'shock'.

Adjustment disorder

A more common psychological response to a major stressor such as a serious medical diagnosis is a less severe but more prolonged emotional reaction.

Clinical features

The predominant symptom is usually depression and/or anxiety, which is insufficiently persistent or intense to merit a diagnosis of depressive or anxiety disorder. There may also be anger, aggressive behaviour and associated excessive alcohol use. Symptoms develop within a month of the onset of the stress, and their duration and severity reflect the course of the underlying stressor.

'Pathological grief' describes a grief reaction that is abnormally intense or persistent, and such abnormalities are a particular type of adjustment disorder. They manifest as a brief period of emotional numbing, followed by a period of distress lasting several weeks, during which sorrow, tearfulness, sleep disturbance, a sense of futility, anger and 'bargaining' are common. Perceptual distortions may occur, including misinterpreting sounds as the dead person's voice or 'seeing' the dead person.

Diagnosis

The diagnosis is made on the basis of the typical history, with a strong presumed relationship between the stressful life event and the onset of symptoms described above.

Management

Ongoing contact with and support from a doctor or another person who can listen, reassure, explain and advise are often all that is needed. Most patients do not require psychotropic medication, although benzodiazepines reduce arousal and they (as well as antidepressants) can aid sleep.

Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) is a delayed and/or protracted response to a stressful event of a life-threatening or catastrophic nature. Examples of such events include natural disasters, terrorist activity, serious accidents and witnessing violent deaths. It may also sometimes occur after distressing medical treatments or admissions to intensive care.

Clinical features

The development of PTSD is usually delayed from a few days to several months between the traumatic event and the onset of symptoms. Typical symptoms are recurrent intrusive memories (flashbacks) of the trauma; sleep disturbance, especially nightmares (usually of the traumatic event) from which the patient awakes in a state of anxiety; symptoms of autonomic arousal (anxiety, palpitations, enhanced startle); emotional numbing; and avoidance of situations that evoke memories of the trauma. Anxiety and depression are often associated and excessive use of alcohol or drugs frequently complicates the clinical picture.

Diagnosis

The diagnosis is made on the basis of the typical clinical features following a traumatic life event.

Management

In the immediate aftermath of a significant trauma, the main aim is to provide support, direct advice and the opportunity for emotional catharsis (routine debriefing may actually be harmful). In established PTSD, structured psychological approaches (CBT, eye movement desensitisation and reprocessing (EMDR) and stress management) are effective. Antidepressant drugs are moderately effective.

Prognosis

Most patients recover within 2–3 years. In a small proportion, the symptoms become chronic.

Eating disorders

There are two well-defined eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN); they share some overlapping features. Ninety percent of people affected are female. There is a much higher prevalence of abnormal eating behaviour in the population that does not meet diagnostic criteria for AN or BN, but may attract a diagnostic label such as 'binge eating disorder'.

Anorexia nervosa

The lifetime risk of anorexia nervosa for women living in Europe is approximately 1%–2% (for men it is < 0.5%), with a peak age of onset of 15–19 years. Predisposing factors include familiality (both genetic and shared environmental factors appear to play a role) and 'neurotic' personality traits. The illness is often precipitated by weight loss, whether due to non-pathological dieting/increased exercise or physical illness such as gastrointestinal disorders or type 1 diabetes. Many sufferers do not engage with specialist services and it is not uncommon for the first presentation to be with a medical problem (Box 29.26) rather than to psychiatric services.

Clinical features

There is marked weight loss, arising from food avoidance, often in combination with bingeing, purging, excessive exercise and/or the use of diuretics and laxatives. Body image is profoundly disturbed so that, despite emaciation, patients still feel overweight and are terrified of weight gain. These preoccupations are intense and pervasive, and the false beliefs may be held with a conviction approaching the delusional. Anxiety and depressive symptoms are common accompaniments. Downy hair (lanugo) may develop on the back, forearms and cheeks. Extreme starvation is associated with a wide range of physiological and pathological bodily changes. All organ systems may be affected, although the most serious problems are cardiac and skeletal (see Box 29.26).

Pathogenesis

The underlying cause is unclear but probably includes personality (high neuroticism), genetic (twin studies indicate heritability of 0.3–0.5) and

29.26 Medical consequences of eating disorders

Cardiac

- ECG abnormalities: T-wave inversion, ST depression and prolonged QTc interval
- Arrhythmias, including profound sinus bradycardia and ventricular tachycardia

Haematological

- Anaemia, thrombocytopenia and leucopenia

Endocrine

- Pubertal delay or arrest
- Growth retardation and short stature
- Amenorrhoea
- Sick euthyroid state

Metabolic

- Uraemia
- Renal calculi
- Osteoporosis

Gastrointestinal

- Constipation
- Abnormal liver function tests

29.27 Diagnostic criteria for eating disorders

Anorexia nervosa

- Weight loss of at least 15% of total body weight (or body mass index ≤ 17.5 kg/m^2)
- Avoidance of high-calorie foods
- Distortion of body image so that patients regard themselves as fat even when grossly underweight
- Amenorrhoea for at least 3 months

Bulimia nervosa

- Recurrent bouts of binge eating
- Lack of self-control over eating during binges
- Self-induced vomiting, purgation or dieting after binges
- Weight maintained within normal limits

environmental factors, including, in many societies, the social pressure on women to be thin.

Diagnosis

Diagnostic criteria are shown in Box 29.27. Differential diagnosis is from other causes of weight loss, including psychiatric disorders such as depression, and medical conditions such as inflammatory bowel disease, malabsorption, hypopituitarism and cancer, although it is important to remember that AN can coexist with any of these. The diagnosis is based on a pronounced fear of fatness despite being thin, and on the absence of an adequate alternative explanation for weight loss.

Management

The aims of management are to ensure patients' physical well-being while helping them to gain weight by addressing the beliefs and behaviours that maintain the low weight. Treatment is usually given on an outpatient basis. Inpatient treatment should be reserved for those at risk of death from medical complications or from suicide. There is a limited evidence base for CBT-based psychological treatments. Family behaviour therapy has efficacy for adolescent, but not adult patients. Psychotropic drugs are of no proven benefit in AN, but antidepressant medication may be indicated in those with clear-cut comorbid depressive disorder.

Weight gain is best achieved in a collaborative fashion. Compulsory admission and refeeding (including tube feeding) are very occasionally resorted to when patients are at risk of death and other measures have failed. While this may produce a short-term improvement in weight, it rarely changes long-term prognosis.

Prognosis

Two-thirds of patients with AN no longer meet diagnostic criteria at 5-year follow-up. However, long-term follow-up studies suggest that many sufferers continue to have a relatively low body mass index (BMI), suggesting that the symptoms do not completely resolve. Approximately 20% of patients develop a chronic, intractable disorder. Long-term follow-up studies demonstrate that minimum lifetime BMI is the strongest prognostic indicator (BMI < 11.5 kg/m^2 is associated with a standardised mortality ratio of 4–5). Other indicators of poor prognosis are comorbid BN and atypical demographics (very early or relatively late onset, male gender). Forty percent of additional deaths are due to suicide, the remainder being due to complications of starvation.

Bulimia nervosa

The prevalence of BN is difficult to determine with precision, as only a small proportion of sufferers come to medical attention. It is believed to be more common than AN, with a similar gender ratio. Peak age of onset is slightly later than for AN, typically late adolescence or early adult life.

Clinical features

Patients with BN are usually at or near normal weight (unlike in AN), but display a morbid fear of fatness associated with disordered eating behaviour. They recurrently embark on eating binges, often followed by corrective measures such as self-induced vomiting.

Diagnosis

Diagnostic criteria are shown in Box 29.27. Physical signs of repeated self-induced vomiting include pitted teeth (from gastric acid), calluses on knuckles ('Russell sign') and parotid gland enlargement. There are many associated physical complications, including the dental and oesophageal consequences of repeated vomiting, as well as electrolyte abnormalities, cardiac arrhythmias and renal problems (see Box 29.26).

Investigations

Self-induced vomiting and/or abuse of laxatives and diuretics can lead to clinically significant electrolyte disturbances, including hypokalaemia leading to cardiac arrhythmias. Hence it is good practice to measure urea and electrolytes and obtain an ECG whenever these behaviours are prominent in any patient and when BN is suspected in any medical inpatient. Repeated vomiting can also give rise to Mallory–Weiss tears and even oesophageal rupture.

Management

Treatment of bulimia with CBT achieves both short-term and long-term improvements. Guided self-help and IPT may also be of value. There is also evidence for benefit from the SSRI fluoxetine, but high doses of up to 60 mg daily may be required for a prolonged period of up to 1 year; this appears to be independent of the antidepressant effect.

Prognosis

Bulimia is not associated with increased mortality, but a proportion of sufferers go on to develop anorexia. At 10-year follow-up, approximately 10% are still unwell, 20% have a subclinical degree of bulimia, and the remainder have recovered.

Disorders of bodily distress or bodily experience

The essential feature of these disorders is that the patient experiences distressing bodily ('somatic') symptoms that are not adequately explained by a medical condition (medically unexplained symptoms, MUS), nor better diagnosed as part of a depressive or anxiety disorder. The sufferer directs excessive attention towards their bodily symptoms.

Several syndromes are described within this category; there is considerable overlap between them, both in the underlying causes and in the clinical presentation. Some patients experience a range of symptoms that may vary over time, others focus on a single symptom, such as pain or fatigue.

Pathogenesis

The cause of bodily distress disorders is incompletely understood, but contributory factors include depression and anxiety, the erroneous interpretation of somatic symptoms as evidence of disease, excessive concern with physical illness and a tendency to seek medical care. A family history or previous history of a particular condition may have shaped the patient's beliefs about illness. Doctors may exacerbate the problem, either by dismissing the complaints as non-existent or by over-emphasising and investigating the possibility of disease.

Clinical features

Bodily distress disorders can present in several different ways, as described below.

Somatoform autonomic dysfunction

This describes somatic symptoms referable to bodily organs that are largely under the control of the autonomic nervous system. The most common examples involve the cardiovascular system ('cardiac neurosis'), respiratory system ('psychogenic hyperventilation') and gut ('psychogenic vomiting' and 'irritable bowel syndrome'). Antidepressant drugs and CBT may be helpful.

Somatoform pain disorder

This describes severe, persistent pain that cannot be adequately explained by a medical condition. Antidepressant drugs (especially tricyclics and dual action drugs such as duloxetine) are helpful, as are some of the anticonvulsant drugs, particularly carbamazepine, gabapentin and pregabalin. CBT and multidisciplinary pain management teams are also useful.

Chronic fatigue syndrome

Chronic fatigue syndrome (CFS) is characterised by excessive fatigue after minimal physical or mental exertion, poor concentration, dizziness, muscular aches and sleep disturbance. This pattern of symptoms may follow a viral infection such as infectious mononucleosis, influenza or hepatitis. Symptoms overlap with those of depression and anxiety. There is good evidence that many patients improve with carefully graded exercise and with CBT, as long as the benefits of such treatment are carefully explained.

Somatisation disorder

This is a severe form of bodily distress disorder where the patient experiences multiple medically unexplained physical symptoms affecting several bodily systems over many years. It is also known as Briquet syndrome after the physician who first described the presentation. Symptoms often start in early adult life, but somatisation disorder can arise later, usually following an episode of physical illness. The disorder is more common in women. Patients may undergo a multitude of negative investigations and unhelpful operations, particularly hysterectomy and cholecystectomy. There is no proven treatment except to try to ensure that unnecessary investigations and surgical procedures are avoided, to minimise iatrogenic harm.

Dissociative disorders

Dissociative disorders are characterised by a loss or distortion of neurological functioning that is not fully explained by organic disease ('functional neurological disorder'). These may be psychological functions such as memory ('dissociative amnesia'), sensory functions such as vision ('dissociative blindness'), or motor functions ('functional gait disorder'; p. 1183) (Box 29.28). The cause is unknown, but there is an association with recent stress and with adverse childhood experiences, including physical and sexual abuse. Organic disease may precipitate dissociation and provide a model for symptoms. For example, non-epileptic seizures often occur in those with epilepsy. Treatment with CBT may be of benefit.

Health anxiety disorder ('hypochondriasis')

Patients with this condition have a strong fear or belief that they have a serious, often fatal, disease (such as cancer), and that fear persists despite appropriate medical reassurance. They are typically highly anxious and seek many medical opinions and investigations in futile, but repeated attempts to relieve their fears. Health anxiety disorder often resembles OCD, but in a small proportion of cases the conviction that disease is present reaches delusional intensity. The best-known example is that of parasitic infestation ('delusional parasitosis'), which leads patients to consult dermatologists. Treatment with CBT can be helpful. Patients who suffer delusions may benefit from antipsychotic medication. The condition may become chronic.

Body dysmorphic disorder

This is defined as a preoccupation with bodily shape or appearance, with the belief that one is disfigured in some way. People with this condition may make inappropriate requests for cosmetic surgery. Treatment with CBT or antidepressants may be helpful. The belief in disfigurement may sometimes be delusional, in which case antipsychotic drugs can help.

29.28 Common presentations of dissociative disorder

- Gait disturbance
- Loss of function in limbs
- Aphonia
- Non-epileptic seizures
- Sensory loss
- Blindness

29.29 General management principles for medically unexplained symptoms

- Take a full sympathetic history
- Exclude disease but avoid unnecessary investigation or referral
- Seek specific treatable psychiatric syndromes
- Demonstrate to patients that you believe their complaints
- Establish a collaborative relationship
- Give a positive explanation for the symptoms, including but not overemphasising psychological factors
- Encourage a return to normal functioning

Body integrity dysphoria

This describes intense and persistent discomfort about one's current body configuration or functioning leading to a desire to 'correct' this, even if that will result in significant physical disability (e.g. wishing to have a limb removed). Patients may present requesting surgery or even following self-injurious attempts to reconfigure their body.

Management

The management of the various syndromes of medically unexplained complaints described above is based on the general principles outlined in Box 29.29 and discussed in more detail below.

Reassurance

Patients should be asked what they are most worried about. Clearly, it may be unwise to state categorically that the patient does not have any disease, as that is difficult to establish with certainty. However, it can be emphasised that the probability of having a disease is low and that doctors often see patients with physical symptoms but no physical disease. If patients repeatedly ask for reassurance about the same health concern despite reassurance, they may have hypochondriacal disorder.

Explanation

Patients need a positive explanation for their symptoms. It is unhelpful to say that symptoms are psychological or 'all in the mind'. Rather, a term such as 'functional' (meaning that the symptoms represent a reversible disturbance of bodily function) may be more acceptable. When possible, it is useful to describe a plausible physiological mechanism that is linked to psychological factors such as stress and implies that the symptoms are reversible. For example, in irritable bowel syndrome, psychological stress results in increased activation of the autonomic nervous system, which leads to constriction of smooth muscle in the gut wall, which in turn causes pain and bowel disturbance.

Advice

This should focus on how to overcome factors perpetuating the symptoms: for example, by resolving stressful social problems or by practising relaxation. The doctor can offer to review progress, to prescribe (for example) an antidepressant drug and, if appropriate, to refer for physiotherapy or psychological treatments such as CBT. The attitudes of relatives may need to be addressed if they have adopted an over-protective role, unwittingly reinforcing the patient's disability.

Drug treatment

Antidepressant drugs are often helpful, even if the patient is not depressed.

Psychological treatment

There is evidence for the effectiveness of CBT. Other psychological treatments such as IPT may also have a role.

Rehabilitation

Where there is chronic disability, particularly in dissociative (conversion) disorder, conventional physical rehabilitation may be the best approach.

Shared care

Ongoing planned care is required for patients with chronic intractable symptoms, especially those of somatisation disorder. Review by the same specialist, interspersed with visits to the same GP, is probably the best way to avoid unnecessary multiple re-referral for investigation, to ensure that treatable aspects of the patient's problems, such as depression, are actively managed and to prevent the GP from becoming demoralised.

Alcohol misuse and dependence

Alcohol consumption associated with social, psychological and physical problems constitutes misuse. The criteria for alcohol dependence, a more restricted term, are shown in Box 29.30. Approximately one-quarter of male patients in general hospital medical wards in the UK have a current or previous alcohol problem.

Pathogenesis

Availability of alcohol and social patterns of use appear to be the most important factors. Genetic factors predispose to dependence. The majority of people who misuse alcohol do not have an associated psychiatric disorder, but a few drink heavily in an attempt to relieve anxiety or depression.

Clinical features

The modes of presentation of alcohol misuse and complications are summarised below.

Social problems

Common features include absenteeism from work, unemployment, marital tensions, child abuse, financial difficulties and problems with the law, such as violence and traffic offences.

Low mood

Low mood is common since alcohol has a direct depressant effect and heavy drinking creates numerous social problems. Attempted and completed suicide are associated with alcohol misuse.

Anxiety

People who are anxious may use alcohol as a means of relieving anxiety in the short term and this can develop into dependence. Conversely, alcohol withdrawal increases anxiety.

Alcohol withdrawal syndrome

The features are described in Box 29.31. Symptoms usually become maximal about 2–3 days after the last drink and can include seizures. The term 'delirium tremens' is used to describe severe alcohol withdrawal syndrome characterised by both delirium (characteristically, agitation and visual hallucinations) and physiological hyper-arousal (tremor, sweating and tachycardia). It has a significant mortality and morbidity (see Box 29.31). Management is summarised in Figure 29.3.

29.30 Criteria for alcohol dependence

- Narrowing of the drinking repertoire
- Priority of drinking over other activities (salience)
- Tolerance of effects of alcohol
- Repeated withdrawal symptoms
- Relief of withdrawal symptoms by further drinking
- Subjective compulsion to drink
- Reinstatement of drinking behaviour after abstinence

Hallucinations

Hallucinations (characteristically visual but sometimes in other modalities) are common in delirium tremens. Less common is the phenomenon called 'alcoholic hallucinosis', where a patient with alcohol dependence experiences auditory hallucination in clear consciousness at a time when they are not withdrawing from alcohol.

Wernicke–Korsakoff syndrome

This is a rare but important indirect complication of chronic alcohol misuse. It is an organic brain disorder resulting from damage to the mamillary bodies, dorsomedial nuclei of the thalamus and adjacent areas of periventricular grey matter caused by a deficiency of thiamin (vitamin B_1). The syndrome most commonly results from long-standing heavy drinking and an inadequate diet but can also arise from malabsorption or even protracted vomiting. Wernicke encephalopathy (nystagmus or ophthalmoplegia with ataxia and delirium) often presents acutely and, without prompt treatment (see below), can progress and become irreversible. Korsakoff syndrome (severe short-term memory deficits and confabulation) can develop chronically or acutely (with Wernicke).

Alcohol-related brain damage

The term alcohol-related brain damage (ARBD) is often used as a collective description of the many brain pathologies associated with alcohol excess, which often coexist in the same patient. Acute alcohol intoxication causes ataxia, slurred speech, emotional incontinence and aggression. Very heavy drinkers may experience periods of amnesia for events that occurred during bouts of intoxication, termed 'alcoholic blackouts'. Established alcohol dependence or prolonged harmful use may lead to

29.31 Presentation and consequences of chronic alcohol misuse

Acute intoxication

- Emotional and behavioural disturbance
- Medical problems: hypoglycaemia, ketoacidosis, aspiration of vomit, respiratory depression
- Accidents, injuries sustained in fights

Withdrawal phenomena

- Psychological symptoms: restlessness, anxiety, panic attacks
- Autonomic symptoms: tachycardia, sweating, pupil dilatation, nausea, vomiting
- Delirium: agitation, hallucinations (classically 'Lilliputian'), illusions, delusions
- Seizures

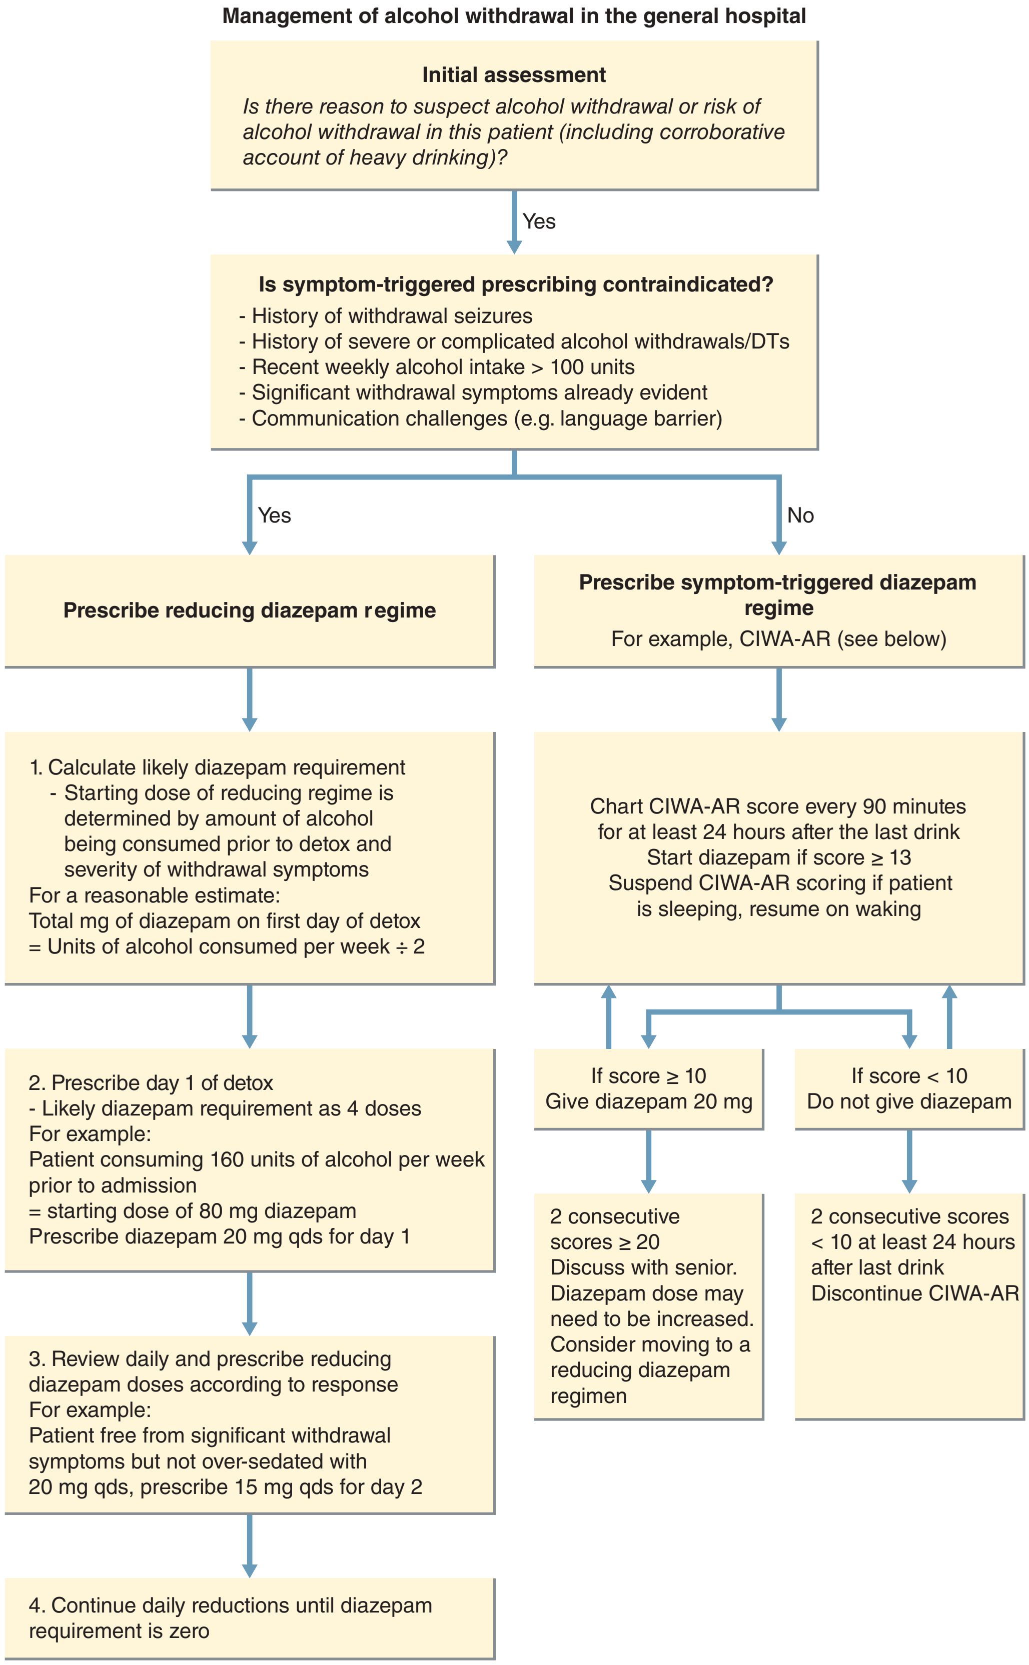
Consequences of harmful use

Medical

- Neurological: peripheral neuropathy, cerebellar degeneration, cerebral haemorrhage, dementia
- Hepatic: fatty change and cirrhosis, liver cancer
- Gastrointestinal: oesophagitis, gastritis, pancreatitis, oesophageal cancer, Mallory–Weiss syndrome, malabsorption, oesophageal varices
- Respiratory: pulmonary tuberculosis, pneumonia
- Skin: spider naevi, palmar erythema, Dupuytren contractures, telangiectasias
- Cardiac: cardiomyopathy, hypertension
- Musculoskeletal: myopathy, fractures
- Endocrine and metabolic: pseudo-Cushing syndrome, hypoglycaemia, gout
- Reproductive: hypogonadism, fetal alcohol syndrome, infertility

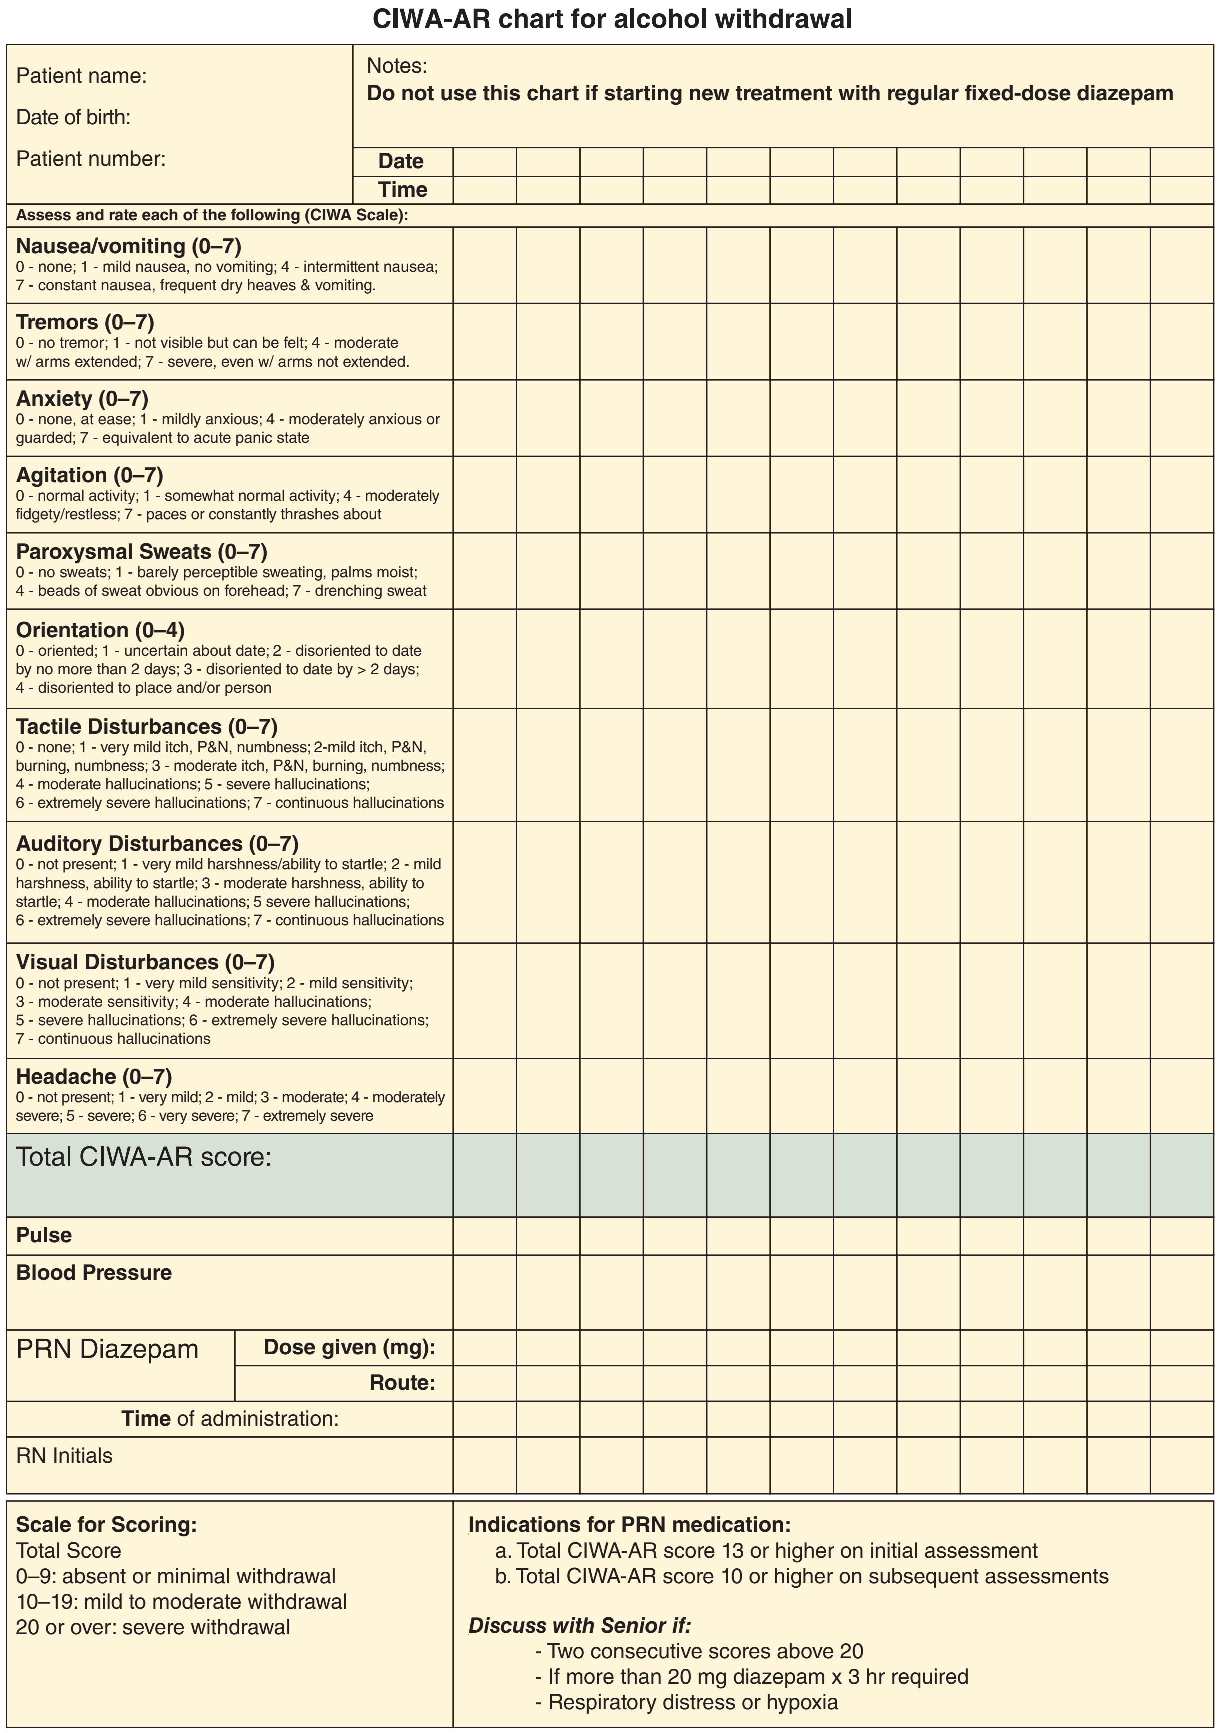
Psychiatric and cerebral

- Depression
- Alcoholic hallucinosis
- Alcoholic 'blackouts'
- Wernicke encephalopathy: nystagmus or ophthalmoplegia with ataxia and delirium
- Korsakoff syndrome: short-term memory deficits leading to confabulation



Management of alcohol withdrawal in the general hospital
Initial assessment
Is there reason to suspect alcohol withdrawal or risk of alcohol withdrawal in this patient (including corroborative account of heavy drinking)?
Yes
Is symptom-triggered prescribing contraindicated?
- History of withdrawal seizures
- History of severe or complicated alcohol withdrawals/DTs
- Recent weekly alcohol intake > 100 units
- Significant withdrawal symptoms already evident
- Communication challenges (e.g. language barrier)
Yes
No
Prescribe reducing diazepam regime
Prescribe symptom-triggered diazepam regime
For example, CIWA-AR (see below)
1. Calculate likely diazepam requirement
- Starting dose of reducing regime is determined by amount of alcohol being consumed prior to detox and severity of withdrawal symptoms
For a reasonable estimate:
Total mg of diazepam on first day of detox
= Units of alcohol consumed per week ÷ 2
Chart CIWA-AR score every 90 minutes for at least 24 hours after the last drink
Start diazepam if score ≥ 13
Suspend CIWA-AR scoring if patient is sleeping, resume on waking
2. Prescribe day 1 of detox
- Likely diazepam requirement as 4 doses
For example:
Patient consuming 160 units of alcohol per week prior to admission
= starting dose of 80 mg diazepam
Prescribe diazepam 20 mg qds for day 1
If score ≥ 10
Give diazepam 20 mg
If score < 10
Do not give diazepam
2 consecutive scores ≥ 20
Discuss with senior.
Diazepam dose may need to be increased.
Consider moving to a reducing diazepam regimen
2 consecutive scores < 10 at least 24 hours after last drink
Discontinue CIWA-AR
3. Review daily and prescribe reducing diazepam doses according to response
For example:
Patient free from significant withdrawal symptoms but not over-sedated with 20 mg qds, prescribe 15 mg qds for day 2
4. Continue daily reductions until diazepam requirement is zero

Fig. 29.3 **Management of acute alcohol withdrawal in the general hospital.** (CIWA-AR = Clinical Institute Withdrawal Assessment for Alcohol Revised; DTs = delirium tremens; qds = 4 times daily; P&N = pins and needles; PRN = as needed)



CIWA-AR chart for alcohol withdrawal

Patient name:

Date of birth:

Patient number:

Notes:
Do not use this chart if starting new treatment with regular fixed-dose diazepam

Date												
Time												
Assess and rate each of the following (CIWA Scale):												
Nausea/vomiting (0–7) 0 - none; 1 - mild nausea, no vomiting; 4 - intermittent nausea; 7 - constant nausea, frequent dry heaves & vomiting.												
Tremors (0–7) 0 - no tremor; 1 - not visible but can be felt; 4 - moderate w/ arms extended; 7 - severe, even w/ arms not extended.												
Anxiety (0–7) 0 - none, at ease; 1 - mildly anxious; 4 - moderately anxious or guarded; 7 - equivalent to acute panic state												
Agitation (0–7) 0 - normal activity; 1 - somewhat normal activity; 4 - moderately fidgety/restless; 7 - paces or constantly thrashes about												
Paroxysmal Sweats (0–7) 0 - no sweats; 1 - barely perceptible sweating, palms moist; 4 - beads of sweat obvious on forehead; 7 - drenching sweat												
Orientation (0–4) 0 - oriented; 1 - uncertain about date; 2 - disoriented to date by no more than 2 days; 3 - disoriented to date by > 2 days; 4 - disoriented to place and/or person												
Tactile Disturbances (0–7) 0 - none; 1 - very mild itch, P&N, numbness; 2-mild itch, P&N, burning, numbness; 3 - moderate itch, P&N, burning, numbness; 4 - moderate hallucinations; 5 - severe hallucinations; 6 - extremely severe hallucinations; 7 - continuous hallucinations												
Auditory Disturbances (0–7) 0 - not present; 1 - very mild harshness/ability to startle; 2 - mild harshness, ability to startle; 3 - moderate harshness, ability to startle; 4 - moderate hallucinations; 5 severe hallucinations; 6 - extremely severe hallucinations; 7 - continuous hallucinations												
Visual Disturbances (0–7) 0 - not present; 1 - very mild sensitivity; 2 - mild sensitivity; 3 - moderate sensitivity; 4 - moderate hallucinations; 5 - severe hallucinations; 6 - extremely severe hallucinations; 7 - continuous hallucinations												
Headache (0–7) 0 - not present; 1 - very mild; 2 - mild; 3 - moderate; 4 - moderately severe; 5 - severe; 6 - very severe; 7 - extremely severe												
Total CIWA-AR score:												
Pulse												
Blood Pressure												
PRN Diazepam **Dose given (mg):**												
Route:												
Time of administration:												
RN Initials												

Scale for Scoring:
Total Score
0–9: absent or minimal withdrawal
10–19: mild to moderate withdrawal
20 or over: severe withdrawal

Indications for PRN medication:
a. Total CIWA-AR score 13 or higher on initial assessment
b. Total CIWA-AR score 10 or higher on subsequent assessments

Discuss with Senior if:
- Two consecutive scores above 20
- If more than 20 mg diazepam x 3 hr required
- Respiratory distress or hypoxia

Fig. 29.3, cont'd

'alcohol-related brain damage' (ARBD), a global cognitive impairment resembling Alzheimer disease, but which does not progress and may even improve if the patient becomes abstinent. Heavy alcohol use can damage the brain indirectly through Wernicke–Korsakoff syndrome (see above), head injury, hypoglycaemia and encephalopathy.

Effects on other organs

These are protean and virtually any organ can be involved (see Box 29.31). These effects are discussed in detail in other chapters in this book.

Diagnosis

The diagnosis of alcohol excess may emerge while taking the patient's history, but many patients do not tell the truth about their alcohol intake. Alcohol misuse may also present through its effects on one or more aspects of the patient's life, as listed above. Alcohol dependence commonly presents with withdrawal in those admitted to hospital, as they can no longer maintain their high alcohol intake in this setting.

Management

For the person misusing alcohol, provision of clear information from a doctor about the harmful effects of alcohol and safe levels of consumption is often all that is needed. In more serious cases, patients may have to be advised to alter leisure activities or change jobs to help them to reduce their consumption. Psychological treatment is used for people who have recurrent relapses and is usually available at specialised centres. Support to stop drinking is also provided by voluntary organisations, such as Alcoholics Anonymous (AA) in the UK.

Alcohol withdrawal syndromes can be prevented, or treated once established, with long-acting benzodiazepines prescribed either as a pre-determined reducing regimen or using a symptom-triggered prescribing tool such as the Clinical Institute Withdrawal Assessment for Alcohol Revised (CIWA-AR). Large doses of benzodiazepines may be required, typically tailed off over a period of 5–7 days as symptoms subside (see Fig. 29.3). Prevention of the Wernicke–Korsakoff syndrome requires the immediate use of high doses of thiamin, which is initially given parenterally (for 48 hrs, longer if symptoms persist) and then orally (100 mg 3 times daily). There is no treatment for Wernicke–Korsakoff syndrome once it has arisen. The risk of side-effects, such as respiratory depression with benzodiazepines and anaphylaxis with intravenous thiamin, is small when weighed against the potential benefits of treatment.

Acamprosate (666 mg 3 times daily) may help to maintain abstinence by reducing the craving for alcohol. Disulfiram (200–400 mg daily) can be given as a deterrent to patients who have difficulty resisting the impulse to drink after becoming abstinent. It blocks the metabolism of alcohol, causing acetaldehyde to accumulate. When alcohol is consumed, an unpleasant reaction follows, with headache, flushing and nausea. Disulfiram is always an adjunct to other treatments, especially supportive psychotherapy. Treatment with antidepressants may be required if depression is severe or does not resolve with abstinence. Antipsychotics, such as chlorpromazine (100 mg 3 times daily), are needed for alcoholic hallucinosis. Although such treatment may be successful, there is a high relapse rate.

Prognosis

Between 80% and 90% of patients with established alcohol dependence syndrome who embark on medically supervised detoxification will successfully complete detoxification without encountering significant complications. Sustaining abstinence is more challenging than achieving it, however. Studies indicate that 1 year after successful detoxification, only 20% of patients will remain abstinent. This figure rises to approximately 30% for patients who are engaged with alcohol services, and to over 40% if such specialist support is combined with supervised disulfiram treatment.

Substance misuse disorder

Dependence on and misuse of both illegal and prescribed drugs is a major problem worldwide. Drugs of misuse are described in detail in Chapter 11. They can be grouped as follows.

Sedatives

These commonly give rise to physical dependence, the manifestations of which are tolerance and a withdrawal syndrome. Drugs include benzodiazepines, opiates (including morphine, heroin, methadone and dihydrocodeine) and barbiturates (now rarely prescribed). Overdosage with sedatives can be fatal, primarily as a result of respiratory depression (Ch. 11). Withdrawal from opiates is notoriously unpleasant, and withdrawal from benzodiazepines and barbiturates can cause prolonged anxiety and even hallucinations and/or seizures.

Intravenous opiate users are prone to bacterial infections, hepatitis B, hepatitis C and HIV infection through needle contamination. Accidental overdose is common, mainly because of the varied and uncertain potency of illicit supplies of the drug. The withdrawal syndrome, which can start within 12 hours of last use, presents with intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Stimulants

Stimulant drugs include amphetamines and cocaine. They are less dangerous than the sedatives in overdose, although they can cause cardiac and cerebrovascular problems through their pressor effects. Physical dependence syndromes do not arise, but withdrawal causes a rebound lowering in mood and can give rise to an intense craving for further use, especially in any form of drug with a rapid onset and offset of effect, such as crack cocaine. Chronic ingestion can cause a paranoid psychosis similar to schizophrenia. A 'toxic psychosis' (delirium) can occur with high levels of consumption. Unpleasant tactile hallucinations described as 'like ants crawling under the skin' (formication) may be prominent in either acute intoxication or withdrawal.

Hallucinogens

The hallucinogens are a disparate group of drugs that cause prominent sensory disturbances. They include cannabis, ecstasy, lysergic acid diethylamide (LSD), *Psilocybin* (magic mushrooms) and a variety of synthetic cannabinoids (as one of the so-called 'legal highs' or 'novel psychoactive substances'). A toxic confusional state can occur after heavy cannabis consumption. Acute psychotic episodes are well recognised, especially in those with a family or personal history of psychosis, and there is evidence that prolonged heavy use increases the risk of developing schizophrenia. Paranoid psychoses have been reported in association with ecstasy. A chronic psychosis has also been documented after regular LSD use.

Organic solvents

Solvent inhalation (glue sniffing) is popular in some adolescent groups. Solvents produce acute intoxication characterised by euphoria, excitement, dizziness and a floating sensation. Further inhalation leads to loss of consciousness; death can occur from the direct toxic effect of the solvent, or from asphyxiation if the substance is inhaled from a plastic bag.

Pathogenesis

Many of the causal factors for alcohol misuse also apply to substance misuse. The main factors are the psychological and behavioural vulnerabilities described above, cultural pressures, particularly within a peer group, and availability of a drug. In the case of some drugs such as opiates, medical over-prescribing has increased their availability, but there has also been a relative decline in the price of illegal drugs. Most drug users take a range of drugs; this is termed 'polydrug misuse'.

Diagnosis

As with alcohol, the diagnosis either may be apparent from the history and examination, or may be made only once the patient presents with a complication. Drug screening of samples of urine or blood can be valuable in confirming the diagnosis, especially if the patient persists in denial.

Management

The first step is to determine whether patients wish to stop using the drug. If they do not, they can still benefit from advice about how to minimise harm from their habit, such as how to obtain and use clean needles for those who inject. For those who are physically dependent on sedative drugs, substitute prescribing (using methadone, for example, in opiate dependence) may help stabilise their lives sufficiently to allow a gradual reduction in dosage until they reach abstinence. Some specialist units offer inpatient detoxification. The medical management of overdose is discussed in Chapter 11. The drug lofexidine, a centrally acting α-agonist, can be useful in treating the autonomic symptoms of opiate withdrawal, as can clonidine, although this carries a risk of hypotension and is best used by specialists. Long-acting opiate antagonists, such as naltrexone, may also have a place, again in specialist hands, in blocking the euphoriant effects of the opiate, thereby reducing addiction.

In some cases, complete opiate withdrawal is not successful and the patient functions better if maintained on regular doses of oral methadone as an outpatient. This decision to prescribe long-term methadone should be taken only by a specialist, and carried out under long-term supervision at a specialist drug treatment centre.

Substitute prescribing is neither necessary nor possible for the hallucinogens and stimulants, but the principles of management are the same as those that should accompany prescribing for the sedatives. These include identifying problems associated with the drug misuse that may serve to maintain it, and intervening where possible. Intervention may be directed at physical illness, psychiatric comorbidity, social problems or family disharmony.

Relapsing patients and those with complications should be referred to specialist drug misuse services. Support can also be provided by self-help groups and voluntary bodies, such as Narcotics Anonymous (NA) in the UK.

Personality disorders

Personality refers to the set of characteristics and behavioural traits that best describes an individual's patterns of interaction with the world. The intensity of particular traits varies from person to person, although certain ones, such as shyness or irritability, are displayed to some degree by most people. A personality disorder (PD) is diagnosed when an individual's personality causes persistent and severe problems for the person or for others.

Pathogenesis

Some PDs appear to have an inherited aspect (especially schizotypal and paranoid subtypes), but most are more clearly related to adverse childhood experiences.

Clinical features

Personality disorders present in various ways. For example, anxiety may be so pronounced that the individual rarely ventures into any situation where they fear scrutiny. Dissocial traits, such as disregard for the well-being of others and a lack of guilt concerning the adverse effects of one's actions on others, may occur. If pronounced, they may lead to damage to others, to criminal acts or to successful careers, such as in politics. They usually persist throughout life and are not readily treated. While they typically become less extreme with age, they can re-emerge in the context of cognitive decline.

Diagnosis

It is possible to classify PD into several subtypes (such as emotionally unstable, antisocial or dependent), depending on the particular behavioural traits in question. A patient who meets diagnostic criteria for one subtype may also meet criteria for others. As allocation to one particular subtype gives little guidance to management or prognosis, classification is of limited value. Diagnosis requires a longitudinal perspective, with clear evidence that the patient's behavioural traits and patterns of interaction with the world have been present throughout their adult life, have been evident across a range of settings and have caused repeated and persistent problems. It can be difficult to achieve this during a single interview, and most psychiatrists warn against making a diagnosis of personality disorder until the patient has been seen several times and corroborative accounts have been obtained. It is common for PD to accompany other psychiatric conditions, making treatment of the latter more difficult and therefore affecting their prognosis.

Management

Treatment options are limited, but there is some evidence that emotionally unstable PD may respond to dialectical behavioural therapy (DBT). Anxious (avoidant) and obsessional (anankastic) PD may benefit from prescription of anxiolytic drugs, while paranoid/schizotypal PD may be improved by treatment with low doses of antipsychotic agents.

The problematic and inflexible patterns of interaction that characterise a PD are often apparent in the patient's interaction with health services and can present a challenge to both the service and the patient. Clear clinical communication supported by robust documentation can help to minimise any potential disruption.

Factitious disorder

Factitious disorder describes the repeated and deliberate production of the signs or symptoms of disease to obtain medical care.

Pathogenesis

It is difficult to understand what motivates a person to act in this way. Several theories have been proposed but the deception that lies at the heart of the condition makes it difficult to gather accurate data from which to draw reliable conclusions.

Clinical features

The disorder feigned is usually medical, but can be a psychiatric illness (for example, false reports of hallucinations or symptoms of depression). An example of a medical factitious disorder is dipping of a thermometer into a hot drink to fake a fever. Factitious disorder is uncommon and is important to distinguish from bodily distress disorders. A suggested diagnostic algorithm is shown in Figure 29.4.

Münchausen syndrome

This refers to a severe chronic form of factitious disorder. Patients characteristically travel widely, sometimes visiting several hospitals in one day. Although the condition is rare, such patients are memorable because they present so dramatically. The history can be convincing enough to persuade doctors to undertake investigations or initiate treatment, including exploratory surgery. It may be possible to trace the patient's history and show that they have presented similarly elsewhere, often changing name several times. Some emergency departments hold lists of such patients.

Malingering

Malingering is a description of behaviour, not a psychiatric diagnosis. It refers to the deliberate and conscious simulation of signs of disease and disability for an identifiable gain (patients have motives that are clear to them but which they initially conceal from doctors). Examples include the avoidance of burdensome responsibilities (such as work or

court appearances) or the pursuit of financial gain (fraudulent claims for benefits or compensation). Malingering can be hard to detect at clinical assessment, but is suggested by evasion or inconsistency in the history.

Management

Management is by gentle but firm confrontation with clear evidence of the fabrication of illness, together with an offer of psychological support. Treatment is usually declined but recognition of the condition may help to avoid further iatrogenic harm.

Dementia

Dementia is a clinical syndrome characterised by progressive cognitive decline associated with impairment in activities of daily living. It affects 7% of those over 65 and 40% of those over 90. Multiple illnesses can result in the dementia syndrome (Box 29.32), but Alzheimer disease and vascular dementia are the most common. Rarer causes of dementia should be considered in younger patients and those with short histories.

Pathogenesis

Neurodegenerative diseases are often characterised by a clinically silent or 'preclinical' period before the emergence of symptoms, thus Alzheimer *disease* begins decades before Alzheimer *dementia* and the former does not invariably lead to the latter. Up to 45% of dementia risk is potentially modifiable, so risk reduction in midlife is to be advised to all people.

Clinical features

The usual presentation is with a change in memory or another cognitive domain or a disturbance of personality. A careful history is essential and it is important to interview both the patient and an informant (often a close family member), who can provide a collateral history. Cognitive testing is indispensable and a comprehensive bedside test such as the ACE-III should be used; shorter screening tests, such as the MoCA, are useful in other contexts to identify who needs more thorough assessment. In some cases, more intensive neuropsychological assessment may be required, especially if there is diagnostic uncertainty or in someone with high pre-morbid intellectual function. Mental state assessment is important to seek evidence of depression or anxiety, which may coexist with or occasionally cause apparent cognitive impairment. Medication review may reveal polypharmacy or high anticholinergic burden – a common iatrogenic cause of cognitive impairment. Many of the primary degenerative diseases that cause dementia have characteristic features that may allow a specific diagnosis during life. Gradual worsening suggests Alzheimer disease, whereas stepwise deterioration is typical of vascular dementia. Frontotemporal dementias typically present with language disturbance or change in personality and dementia with Lewy bodies may present with visual hallucinations. Creutzfeldt–Jakob disease is usually quickly progressive (over months) and is associated with myoclonus.

Investigations

The aim is to seek treatable causes and to estimate prognosis. This is done using a standard set of investigations (see Box 29.4). Imaging of the brain can exclude potentially treatable structural lesions, such as hydrocephalus, cerebral tumour or chronic subdural haematoma (Fig. 29.5), though the only abnormalities usually seen are generalised atrophy (excessive for age; Fig. 29.6) and cerebrovascular changes. In certain circumstances, more specific imaging may be used, such as FDG PET (Fig. 29.7) or technetium-99m (^{99m}Tc)-HMPAO SPECT, DaTscan (see Fig. 27.46), or amyloid/tau PET. If the initial tests are negative, more invasive investigations, such as lumbar puncture or, very rarely, brain biopsy, may be indicated. Emerging evidence supporting the use of blood-based biomarkers for Alzheimer disease suggests that these may become much more widely used in the future.

29.32 Subtypes and causes of dementia

Type	Common	Less common	Rare
Vascular	Vascular dementia Vascular cognitive impairment Mixed dementia	Cerebral amyloid angiopathy	Cerebral vasculitis Systemic lupus erythematosus
Inherited	Alzheimer disease	Dementia with Lewy bodies Parkinson disease Progressive supranuclear palsy Frontotemporal lobar degeneration syndromes Leukodystrophies Huntington disease Wilson disease Dystrophia myotonica	Mitochondrial encephalopathies Corticobasal degeneration
Neoplastic	Secondary deposits	Primary cerebral tumour	Paraneoplastic syndrome (limbic encephalitis)
Inflammatory	–	Multiple sclerosis	Sarcoidosis
Traumatic	Chronic subdural haematoma Traumatic brain injury	Punch-drunk syndrome	–
Hydrocephalus	–	Communicating/non-communicating ‘normal pressure’ hydrocephalus	–
Toxic/nutritional	Alcohol-related brain damage	Vitamin deficiencies: Thiamin (B_1) Folate (B_9) Vitamin B_{12}	Anoxia/carbon monoxide poisoning Heavy metal poisoning
Infective	–	Syphilis Human immunodeficiency virus (HIV)	Post-encephalitis Whipple disease Subacute sclerosing panencephalitis
Prion diseases	–	Sporadic Creutzfeldt–Jakob disease (CJD)	Variant CJD Kuru Gerstmann–Sträussler–Scheinker disease

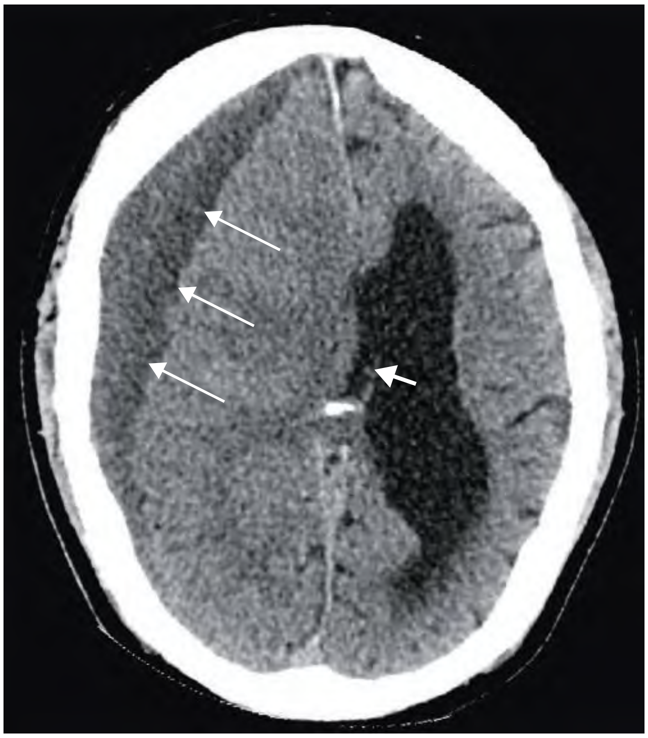

Fig. 29.5 Subdural haematoma. CT head scan demonstrating a large chronic right subdural haematoma (thin white arrows) causing significant mass effect with compression of the right lateral ventricle and midline shift to the left of midline (thick white arrow).

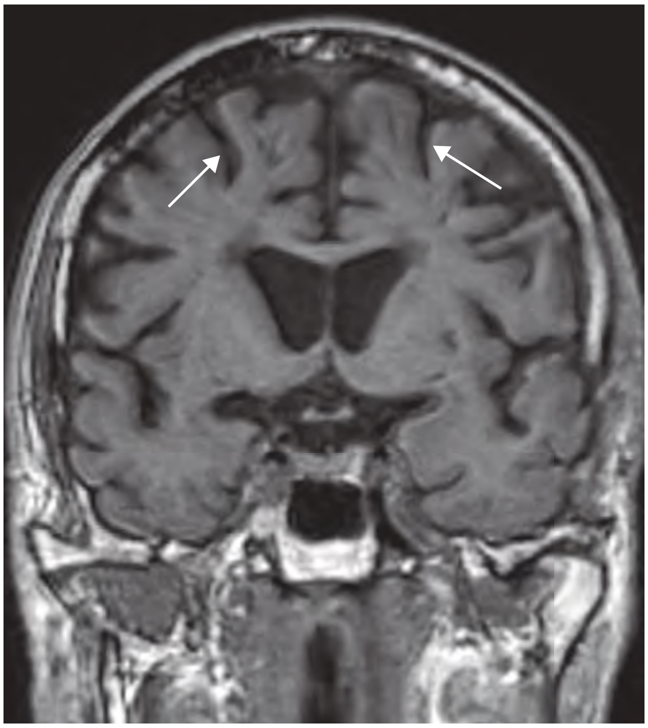

Fig. 29.6 Cerebral atrophy. Coronal T1 MRI head scan in a 45-year-old man demonstrating cerebral atrophy excessive for age with widening of the cerebral sulci (arrows) and ex vacuo dilatation of the collecting system reflecting significant cerebral parenchymal loss.

Management

This should be biopsychosocial and include providing support for patients and carers as well as symptomatic and disease-modifying treatments and secondary prevention. Post-diagnostic information and support should be offered to everyone diagnosed with dementia and their family and should focus on understanding the disease, supporting community connections, peer support, planning for future decision-making and care. Abstinence and vitamin replacement may be recommended in toxic/nutritional dementias. Psychotropic drugs may have a role in alleviating symptoms, such as disturbance of sleep, perception or mood, but should be used with care because of the significant harms associated, particularly antipsychotics. Sedation is not a substitute for good care of patients and carers or, in the later stages, attentive residential nursing care. In the UK, incapacity and mental health legislation may be required later in the disease to manage patients' financial and domestic affairs, as well as to determine their safe placement. As most dementias follow a progressive course, it is good practice to prepare for possible future loss of capacity by encouraging/supporting patients at risk of dementia or with early signs of dementia to make legal and practical arrangements, such as power of attorney, that will provide a proxy decision-maker should they lose the capacity to make decisions for themselves.

Dementia due to Alzheimer disease

Alzheimer disease is the most common cause of dementia and it increases in prevalence with age.

Pathogenesis

Genetic factors are important but complex. Autosomal dominant Alzheimer dementia ($<1\%$ cases) is associated with pathogenic variants in *APP, PSEN1* or *PSEN2* and has young-onset. Late-onset dementia is less heritable, but first-degree relatives of someone with dementia do have an increased risk. Genetic variants in over 50 loci have been identified, but a particularly important genetic risk factor for Alzheimer dementia is the ε4 allele of apolipoprotein E (*APOE* ε4): there is 2–4 times higher risk in heterozygotes and 6–8 times higher risk in homozygotes. Its presence is, however, neither necessary nor sufficient for the development of the disease and so genetic testing for *APOE* ε4 is not clinically useful. The brain in Alzheimer disease is macroscopically atrophic, particularly the cerebral cortex and hippocampus, which is excessive for age. Histologically, the disease is characterised by the presence of extracellular amyloid plaques and intracellular neurofibrillary tangles in the cerebral cortex. However, our understanding of the pathogenesis of Alzheimer disease is far from complete, particularly why some people with moderate or severe Alzheimer disease never develop dementia.

Clinical features

The key clinical feature is a progressive decline in short-term memory, but other cognitive domains are also affected. This is associated with functional impairment in day-to-day activities. Cognitive testing is essential and neuroimaging can be helpful, but neither are diagnostic. In the early stages of the disease, patients may notice their problems, but as the disease progresses it is common for patients to deny that there is anything wrong (anosognosia). Thus, patients are often brought to medical attention by their carers. Clinical features can be made acutely worse by intercurrent physical disease and people with dementia are at high risk of delirium.

Investigations

Investigation is aimed at excluding treatable causes of dementia (see Box 29.32), as definitive histological confirmation of the diagnosis usually occurs only after death.

Management

In addition to the general management for any dementia outlined above, treatment with anticholinesterases, such as donepezil, rivastigmine and galantamine, has been shown to be of some benefit at slowing progression of cognitive impairment in the early stages of Alzheimer dementia while post-synaptic cholinergic receptors are still available. The *N*-methyl-D-aspartate (NMDA) receptor antagonist memantine can also be useful in selected patients with more advanced disease. Evidence of potentially disease-modifying monoclonal antibody treatments is emerging, and these may become more widely available in the near future; aducanumab and lecanemab are available in some countries, and donanemab may obtain a licence. Psychosocial support after a diagnosis can help with symptoms of anxiety or depression, but some patients may also benefit from antidepressant medication, particularly SSRIs. Non-pharmacological approaches include the Newcastle model for behavioural and psychological symptoms, music therapy, attention to environmental factors and support for the carers. Attention should be paid to pain, infection, constipation, and physical health as all these factors, untreated, can cause the patient distress.

Dementia due to cerebrovascular disease

Dementia is common after a stroke – either a large stroke or several smaller strokes – and cognition should always be subsequently assessed. Cerebral small vessel disease – which may be asymptomatic and only identified if a scan is completed – can also be associated with cognitive impairment in all domains and even subcortical vascular dementia. Vascular cognitive impairment of any kind presents a less predictable cognitive profile than other diseases and may progress in a stepwise fashion. Cerebrovascular disease can coexist with other pathologies and is often referred to in such cases as 'mixed dementia'. The mainstay of treatment is secondary prevention: smoking cessation, physical activity, and possibly medication (aspirin or equivalent, antihypertensives and a statin), though potential risks must be weighed up against benefits.

Dementia due to Lewy body disease

This is the second most common neurodegenerative cause of dementia. In addition to the dementia syndrome, the core features of dementia with Lewy bodies (DLB) are fluctuating cognition, recurrent visual hallucinations, rapid eye movement (REM) sleep disorder, and clinical signs of parkinsonism. Diagnosis can be aided by a DaTscan (Fig 27.46). Affected individuals are often particularly sensitive to the side-effects of antipsychotic drugs. In addition to the general treatment for dementia, cholinesterase inhibitors can be helpful in slowing progression of cognitive impairment and are the first-line treatment for visual hallucinations in DLB.

Frontotemporal dementia (FTD)

FTD encompasses several different syndromes characterised by behaviour abnormalities and impairment of language, which usually occur before the age of 65 years. The two major clinical subtypes are behavioural-variant FTD and primary progressive aphasia (PPA). Differentiation from Alzheimer dementia can be helped by an FDG PET (see Fig. 29.7) or ^{99m}Tc-HMPAO SPECT scan. Approximately a quarter of cases are familial but the genetics of FTD are complex – genes implicated including *MAPT* (which encodes microtubule-associated protein tau), *GRN*, *TPD43*, *FUS*, *VCP* and *C9orf72*. The underlying pathology seems to overlap with amyotrophic lateral sclerosis, inclusion body myopathy and Paget disease of bone, suggesting that these disorders share a similar pathogenic basis despite their diverse presentations. Behavioural-variant FTD presents with changes in social functioning and personality. PPA, in contrast, presents with language difficulties that result in difficulties with daily activities. Patients with semantic variant PPA have difficulty naming or understanding single words. In contrast to Alzheimer disease, memory is relatively preserved in the early stages. There is no specific treatment and cholinesterase inhibitors are not effective in FTD. Speech and language therapy can be helpful for PPA. Disinhibition and impulsive behaviours can be helped by SSRIs.

29.33 Psychiatric illness and pregnancy

- **Psychiatric disorder and pregnancy**: always consider effects on mother, fetus and child.
- **Bipolar disorder**: women should have pre-conceptual advice because there is a very high risk of relapse following delivery and some mood stabilisers are teratogenic.
- **Psychiatric treatments and pregnancy**: always make an individual assessment of the risks and benefits taking into consideration effects on mother, fetus and child.
- **Post-partum low mood ('blues')**: weeks 1–3; most cases are transient.
- **Persistent low mood and anhedonia**: may indicate depressive illness.
- **Puerperal psychosis**: progresses rapidly and is an indication for psychiatric admission.

Mental disorders associated with pregnancy

There are three important psychiatric presentations following childbirth. When managing these conditions, it is important always to consider both the mother and the baby, and their relationship (Box 29.33).

Post-partum blues

This is characterised by irritability, labile mood and tearfulness. About 80% of women are affected to some degree. Symptoms begin soon after childbirth, typically peak on about the fourth day and then resolve spontaneously within a few weeks. While the aetiology of post-partum blues is not fully understood, it is likely to be related to hormonal or physiological changes associated with childbirth. No treatment is required, other than to reassure the mother and to remain vigilant for development of post-partum depression.

Post-partum depression

This occurs in 10%–15% of women, with onset typically within a month of delivery (although women often suffer for some time before presenting). It can usually be differentiated from post-partum blues by the duration and severity of the symptoms, in particular anhedonia (loss of capacity for pleasure) and negative thoughts. Risk factors include a previous history of depression, a previous history of post-partum depression, antenatal depression and antenatal anxiety. Unlike depression arising at other times, post-partum depression is not more common in lower socioeconomic groups; the prevalence is similar across all social backgrounds. Diagnosis, explanation and reassurance are important. The usual psychological and drug treatments for depression should be considered to minimise the impact on the mother and child at what is a very important time for both. A number of helpful guidelines are available to inform prescribing decisions (see 'Further information'). The potential risks to both mother and child should be considered and, if hospital admission is required, it should ideally be to a mother and baby unit.

Puerperal psychosis

This has its peak onset in the first 2 weeks after childbirth but can arise several weeks later. It is a rare but serious complication affecting approximately 1 in 500 women. There is a strong association with a personal or familial history of bipolar disorder. It usually takes the form of a manic or depressive psychosis but with sudden onset and fluctuation in severity. Delirium is rare with modern obstetric management but should still be considered in the differential diagnosis. Suspiciousness, concealment and impulsivity are common features of puerperal psychosis; hence the risks to both mother and baby are considerable. The clinical priority is to ensure the safety of both mother and baby and so psychiatric admission, ideally to a psychiatric mother and baby unit, is usually necessary. Pharmacological treatment reflects the clinical picture; antipsychotic medication is almost always indicated, augmented by antidepressants if the picture is of psychotic depression and/or by mood stabilisers if the picture is bipolar. Most women recover but the risk of recurrence following subsequent deliveries is 50%, and some women will progress to psychotic episodes not associated with childbirth, usually bipolar disorder.

Psychiatric disorders during pregnancy

Pregnancy can affect the course of psychiatric illnesses and of bipolar affective disorder in particular. Mood-stabilising drugs such as lithium and sodium valproate, which are prescribed for prophylaxis in bipolar disorder, are teratogenic and should be avoided. Most guidelines recommend deferring conception until mood-stabilising medication is not required, or replacing the mood stabiliser with an antipsychotic such as chlorpromazine. Furthermore, the immediate post-partum period is associated with a dramatically increased risk of relapse in bipolar disorder: studies report relapse rates of up to 60% in the first 3 months after delivery in the absence of prophylactic medication. When relapse occurs following childbirth, not only are the stakes higher than at other times, but also the onset of illness is more rapid, the symptoms more severe and concealment more pronounced. Post-partum relapse of bipolar disorder requires urgent specialist treatment, usually comprising admission to a psychiatric mother and baby unit. Ideally, women with major mental disorders, such as bipolar disorder, should be offered expert pre-conception advice to help them make informed decisions about medication and other aspects of their psychiatric care. A comprehensive post-partum risk management plan should be agreed during pregnancy.

Psychiatry and the law

Medicine takes place in a legal framework, made up of legislation (statute law) drafted by parliament or other governing bodies, precedent built up from court judgements over time (case law) and established tradition (common law). Psychiatry is similar to other branches of medicine in the applicability of common and case law, but differs in that patients with psychiatric disorders can also be subject to legislative requirements to remain in hospital or to undergo treatments they refuse, such as the administration of antipsychotic drugs to a patient with acute schizophrenia who lacks insight and whose symptoms and/or behaviour pose a risk to himself/herself or to others.

The UK has three different Mental Health Acts, covering England and Wales, Scotland and Northern Ireland, and all of these have recently been revised. Other countries may have very different provisions. It is important for practitioners to be familiar with the relevant provisions that apply in their jurisdictions and are likely to arise in the clinical settings in which they work.

All the countries that make up the UK have also introduced Incapacity Acts in recent years, with detailed provisions covering medical treatments for patients incapable of consenting, whether this incapacity arises from physical or mental illness. In general, the guiding principle in British law is that people should be free to make their own decision about any proposed medical treatment, except where their ability to make and/or communicate that decision is demonstrably impaired (by mental illness or physical incapacity). Any restrictions or compulsions applied should be the minimum necessary, they should be applied only for as long as is necessary, and there should be a benefit to the patient that balances the restrictions imposed. There should also be provisions for appeals and oversight.

Multiple Choice Questions

29.1. When assessing cognitive function within the mental state examination, it is good clinical practice to perform which of the following in all patients?

A. A brief assessment of orientation
B. A brief assessment of orientation and attention
C. ACE-III
D. MMSE
E. MoCA

Answer: B.

It is good practice to perform a brief assessment of orientation (place, person and time – the patient is asked their name, age, date of birth, what building they are in, the current date and day of the week) and attention ('serial 7 s' – the patient is asked to subtract 7 from 100 and then 7 from the answer, and so on).

The MoCA (Montreal Cognitive Assessment) and MMSE (Mini-Mental State Examination) are screening questionnaires for cognitive impairment, but these are not necessary in every patient, only those in whom cognitive impairment is suspected. The ACE-III (Addenbrooke's Cognitive Examination, 3rd edition) is a more comprehensive cognitive assessment.

29.2. A 26-year-old beauty therapist presents to the emergency department with an episode of haematemesis. Upper gastrointestinal endoscopy reveals a Mallory–Weiss tear. The patient reports that several times each week for the past 6 months she has been bingeing on crisps and chocolate then making herself sick. Her BMI is 26. What would be appropriate first-line medical investigations?

A. FBC, U&Es, LFTs, albumin, cholesterol, amylase, calcium, magnesium, phosphate, fasting glucose, ECG and bone mineral density scan
B. FBC, U&Es, LFTs, albumin, cholesterol, amylase, calcium, magnesium, phosphate and fasting glucose
C. FBC, U&Es, calcium, magnesium, phosphate, vitamin B_{12}, folate, ferritin and ECG
D. FBC, U&Es, calcium, magnesium, phosphate, B_{12}, folate and ferritin
E. FBC, U&Es, calcium, magnesium, phosphate, B_{12}, folate, ferritin, ECG and bone mineral density scan

Answer: C.

The most likely diagnosis is bulimia nervosa. C is a list of the investigations recommended in bulimia nervosa. A is a list of the investigations recommended in anorexia nervosa. ECG is important in patients with bulimia nervosa because acute electrolyte disturbance can be sufficiently severe to cause potentially dangerous cardiac arrhythmias.

U&Es, calcium, magnesium and phosphate are the electrolytes most commonly disturbed in patients with bulimia nervosa, and chronic nutritional deficiency can be present even where the patient's weight/BMI is normal (or raised), hence it is wise to check FBC, B_{12}, folate and ferritin. Bone mineral density scan is not usually indicated in a patient with normal or slightly raised BMI unless dietary restriction is a prominent feature.

29.3. In the management of psychiatric disorders, it is good clinical practice to consider strategies with what framework?

A. Bio-psycho-holistic
B. Bio-psycho-social
C. Medico-psycho-holistic
D. Medico-psycho-social

Answer: B.

29.4. An 85-year-old man is admitted to an orthopaedic ward with a fractured neck of femur. When attempting to consent the man for his operation, the surgeon soon realises that the man does not understand that he has fractured his hip, nor even that he is in hospital. What term is used to describe this patient's inability to give informed consent?

A. Cognitive impairment
B. Delirium
C. Dementia
D. Incapacity
E. Mental deficiency

Answer: D.

'Cognitive impairment' is a generic term used to describe any deficit in cognitive function; this man undoubtedly has cognitive impairment. 'Delirium' and 'dementia' are both diagnoses in which cognitive impairment is a prominent feature. This man may be suffering from either or both. 'Mental deficiency' is an outdated term for a failure of intellectual development (the term has been superseded by 'learning disability' and 'mental retardation').

Clinical evaluation in maternal medicine

Take a careful history

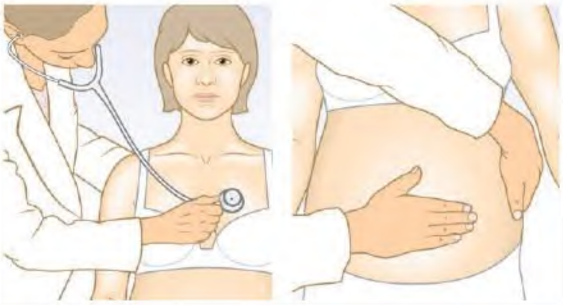
Ask specifically about:
- Cardiac disease
- Renal disease
- Diabetes
- Rheumatic disease
- Inflammatory bowel disease
- Epilepsy

Take a careful drug history

Stop fetotoxic drugs before conception

- Methotrexate
- Leflunomide
- Mycophenolate
- Valproate

Perform general examination



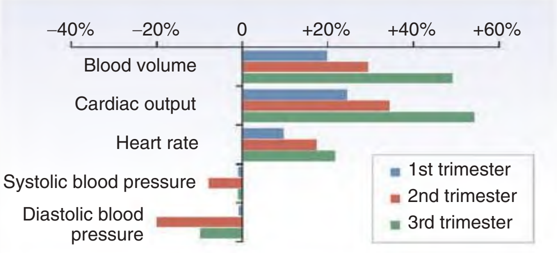
Palmar erythema

Check for anaemia and jaundice

Check for oedema and deep venous thrombosis

Check blood pressure

Consider cardiovascular adaptations during pregnancy



Perform urinalysis

Perform further investigations if appropriate

Perform X-ray imaging if indicated

Remember changes of pregnancy when interpreting laboratory results

- Anaemia
- Altered thyroid function tests
- Low creatinine/urea
- Low CO_2
- Raised alkaline phosphatase
- Glycosuria

Consider mother and fetus when prescribing

Dermatologica Sinica 2016;34:29–32.

Major physiological changes occur during pregnancy, which impact on several organ systems. These are necessary to support the growing fetus, to prepare for delivery and to support lactation. These changes can adversely affect the activity and progression of many pre-existing medical conditions and, in so doing, adversely affect maternal and fetal health. Emphasising this fact, information from the UK Confidential Enquiry into Maternal Deaths has revealed that over recent years, more maternal deaths occur as the result of pre-existing medical conditions than from obstetric causes. The most common causes of death are cardiac disease, neurological disorders and venous thromboembolism. In this chapter we review the physiological changes that occur during pregnancy and the impact of pregnancy on the diagnosis, clinical course and management of common medical conditions. In addition, we review the pathogenesis and management of several medical conditions specific to pregnancy.

Planning pregnancy in patients with medical conditions

Patients with pre-existing medical conditions require careful counselling when planning a pregnancy to make them aware of the risks that pregnancy might pose, as well as the changes in symptoms that might be expected to occur during pregnancy. Although each disease is different, as is discussed later in this chapter, the general principles are to ensure that drugs that may be fetotoxic are stopped before pregnancy is attempted; that high-risk patients are kept under close surveillance during their pregnancy; and that new symptoms that emerge during pregnancy are treated seriously and fully investigated where appropriate.

Functional anatomy and physiology

The most important changes that occur in the anatomy and physiology of major organ systems during pregnancy are discussed below.

Bone metabolism

Major changes in bone metabolism take place to meet the demands of the growing fetus. Intestinal calcium absorption increases, due in part to increased production of 1,25-dihydroxyvitamin D (1,25$(OH)_2$D). Calcium is also released from the maternal skeleton due to increased bone resorption, stimulated by production of parathyroid hormone–related protein (PTHrP) by breast and placenta. This results in loss of bone from the maternal skeleton during pregnancy that continues until lactation ceases and then recovers. Serum concentrations of alkaline phosphatase (ALP) can increase by up to fourfold, but this is due to release of ALP from the placenta rather than bone.

Cardiovascular system

Heart rate and stroke volume increase during pregnancy; when combined with peripheral vasodilatation and a reduction in systemic blood pressure, this causes a hyperdynamic circulatory state and an increase in cardiac output. Diaphragmatic elevation may affect the electrocardiogram (ECG), causing left axis deviation of up to 15°. Other changes include T-wave inversion in leads III and aVF, ST depression, small Q waves and a sinus tachycardia. Supraventricular and ventricular beats are common. Echocardiography shows a modest increase in the dimensions of the cardiac chambers.

Endocrine system

During early pregnancy there is secretion of human chorionic gonadotrophin (hCG) by trophoblast cells, which acts on the corpus luteum in the ovary to stimulate oestradiol and progesterone production (Fig. 30.1). Levels of hCG rise rapidly during early pregnancy to reach a peak around 8 weeks, and then fall before stabilising at a lower level from 20 weeks until term. There is a progressive rise in oestradiol and progesterone levels; initially, these hormones are produced by the corpus luteum, but placental production takes over after about 12 weeks. The high levels of gonadal hormones suppress pituitary gonadotrophin production, but prolactin levels rise about 10-fold, and there is an increase in volume of the anterior pituitary. Serum levels of free T4 increase during the first trimester but, paradoxically, thyroid-stimulating hormone (TSH) levels fall by almost 50%. This is because hCG is homologous to TSH and mimics the effect of TSH on the thyroid, stimulating both T3 and T4 production. The raised levels of T3 and T4 feed back to the pituitary and reduce TSH secretion. Later in pregnancy, there is increased degradation of thyroxine by the placenta and levels of thyroxine-binding globulin (TBG) rise, causing the normal range for free T4 and T3 to fall progressively during pregnancy. Although TSH levels are difficult to interpret early in pregnancy, they provide the best measure of thyroid function after about 16 weeks' gestation.

Gastrointestinal system

The high levels of progesterone during pregnancy lead to relaxation of smooth muscle in the gastrointestinal tract. This causes the lower oesophageal sphincter to relax, predisposing to gastro-oesophageal reflux and reduced gastrointestinal transit; this in turn leads to delayed gastric emptying and constipation.

Genitourinary system

Glomerular filtration rate (GFR) increases during pregnancy due to an increased cardiac output. By the second trimester, renal perfusion increases by up to 80% and GFR by 50%, leading to a fall in serum urea and creatinine. Mild glycosuria may be observed during normal pregnancy due mainly to an increase in filtered load of glucose. The ureters and renal pelvis are slightly dilated, most prominently on the left side, leading to the physiological hydronephrosis of pregnancy.

Glucose metabolism

Maternal glucose metabolism changes during pregnancy to optimise delivery of glucose and other nutrients to the fetus. During the second half of pregnancy in particular, there is maternal insulin resistance due largely to an increase in circulating levels of human placental lactogen (hPL) (see Fig. 30.1). The net effect is to ensure that glucose is preferentially supplied to the fetus rather than the mother. Following delivery of the placenta, there is a rapid decline in hPL and reversal of insulin resistance. During pregnancy, fasting plasma glucose decreases slightly, while post-prandial blood glucose may increase. Glycosuria may occur, even in women who do not have diabetes, due to the increased GFR. Insulin secretion in the fetus is driven by fetal glucose levels, which in turn are dependent on maternal glucose concentrations. Accordingly, in women with diabetes, maternal hyperglycaemia stimulates fetal insulin secretion, which increases fetal growth, resulting in increased birth weight or macrosomia.

Haematological system

Haemoglobin normally falls by about 20% during pregnancy since plasma volume increases more than red cell volume: the so-called physiological anaemia of pregnancy. The reduction in haematocrit lowers blood viscosity, but this is offset by an elevation in levels of several clotting factors, resulting in a hypercoagulable state that increases the risk of venous and arterial thrombosis.

Respiratory system

Tidal volume (TV) increases during pregnancy due to an increased vital capacity and reduced residual volume, and by term the increase in TV

Fig. 30.1 **Hormonal changes in pregnancy.** In early pregnancy, oestradiol and progesterone are mainly derived from the corpus luteum in response to human chorionic gonadotrophin (hCG), secreted by the trophoblast. The raised levels of hCG also act on the thyroid to stimulate T3 (triiodothyronine) and T4 (thyroxine) production, which in turn suppresses thyroid-stimulating hormone (TSH) production by the pituitary. Later in pregnancy, oestradiol and progesterone are derived from the placenta, which also produces human placental lactogen (hPL), impairing glucose tolerance. There is a progressive reduction of free T3 and T4 during pregnancy as the result of T3 and T4 degradation by the placenta and increased secretion of thyroxine-binding globulin (TBG) by the liver.

is about 200 mL. These changes are required to meet the 20% increase in oxygen demand that occurs during pregnancy. The PCO_2 level decreases, but this is offset by an increase in renal excretion of bicarbonate, such that the blood pH remains relatively stable. Respiratory rate is unaffected by pregnancy.

Investigations

The profound changes in physiology and anatomy that occur during pregnancy cause changes in the normal reference ranges for several hormones, electrolytes and other analytes, as summarised in Box 30.1. While many investigations can proceed as normal during pregnancy, invasive procedures should generally be avoided unless the potential benefit clearly outweighs the risk. Investigations that can be performed in pregnancy are shown in Box 30.2.

Imaging

Imaging during pregnancy should be undertaken only when the clinical benefit outweighs the potential risks to mother and fetus. In suspected pulmonary embolus, radionuclide ventilation/perfusion ($\dot{V}/\dot{Q}$) scanning is preferred over computed tomographic pulmonary angiography (CTPA) in women with a normal chest X-ray since $\dot{V}/\dot{Q}$ scans expose the maternal breast and lungs to less radiation than CTPA. However, if the chest X-ray is abnormal, or the patient is unstable, CTPA should be performed, since it is more likely to yield a definitive diagnosis rapidly. The radiation exposure for both investigations is well below the maximum recommended fetal radiation dose in pregnancy (5 rad). Chest X-rays may also be performed safely at any gestation during pregnancy if clinically indicated, since the radiation exposure is very low for the fetus. Magnetic resonance imaging (MRI) is safe in pregnancy and is useful in the assessment of proximal deep vein thrombosis (DVT) and neurological disorders. However, gadolinium-containing contrast agents should be used only if necessary. If gadolinium contrast agents are used in women who are breastfeeding, the milk should be discarded for 24 hours. Ultrasound imaging is safe during pregnancy and useful in the assessment of patients with DVT or intra-abdominal pathology.

Presenting problems in pregnancy

Breathlessness

The causes of breathlessness during pregnancy are summarised in Box 30.3. Many women experience mild breathlessness as part of normal pregnancy, which is known as physiological breathlessness of pregnancy. It is thought to be progesterone-mediated and is classically of gradual onset and present at rest and on exercise. Physiological breathlessness does not require investigation, but severe or persistent breathlessness should be investigated, especially if accompanied by chest pain. The diagnostic approach in pregnant patients with suspected pulmonary embolism differs from that in non-pregnant women. Measurement of D-dimer is not helpful since values normally increase progressively throughout pregnancy. Accordingly, the first-line investigation in suspected pulmonary embolism is a $\dot{V}/\dot{Q}$ scan in a stable patient with a normal chest X-ray, and CTPA in a patient with an abnormal chest X-ray or in a patient who is physiologically unstable.

30.1 Common laboratory changes during pregnancy

Laboratory test	Change	Cause
Haematology		
Haematocrit	Decrease	Extracellular volume expansion
Routine biochemistry		
GFR	Increase	Increased renal blood flow
Urea and creatinine	Decrease	Increased GFR
Alkaline phosphate	Increase	Release by placenta
Glucose	Decrease (fasting) Increase (post-prandial)	Raised insulin Insulin resistance
Hormones		
T4	Increase (first trimester) Decrease (later pregnancy)	Stimulation of thyroid by hCG Placental degradation
TSH	Decrease (first trimester)	Increased T4 due to stimulation of thyroid by hCG
Prolactin	Increase	Increased production by pituitary
Oestradiol	Progressive increase	Production by corpus luteum then placenta
Progesterone	Increase then decrease	
hCG	Progressive increase	Production by trophoblast
hPL		Production by placenta

(GFR = glomerular filtration rate; hCG = human chorionic gonadotrophin; hPL = human placental lactogen; TSH = thyroid-stimulating hormone)

Chest pain

Chest pain does not occur during normal pregnancy, but the incidences of acute coronary syndrome (ACS) and aortic dissection are both increased. Accordingly, if a pregnant woman develops acute severe chest pain suggestive of either of these conditions, she should be investigated and treated in the same way as a non-pregnant woman.

Circulatory collapse

The differential diagnosis of circulatory collapse is wide and causes unrelated to pregnancy are discussed in Chapter 10. Obstetric causes include

30.3 Breathlessness during pregnancy

Cause	Management
Physiological breathlessness of pregnancy	No treatment required
Asthma	Treatment as in non-pregnant women
Pneumonia	Treatment with antibiotic as in non-pregnant women
Valvular heart disease	Treatment as in non-pregnant women
Heart failure	Treatment as in non-pregnant women
Peripartum cardiomyopathy (PPCM)	Treatment as in non-pregnant women Early delivery if haemodynamic deterioration
Pulmonary embolus	Treatment as in non-pregnant women

30.2 Investigations in pregnancy*

Investigation	Use during pregnancy	Comment
Renal biopsy	Can be performed during pregnancy	< 22 weeks is safest; 23–28 weeks is period of highest risk
Upper gastrointestinal endoscopy	Safe during pregnancy Left lateral position is recommended in the second half of pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Colonoscopy	Safe during pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Flexible sigmoidoscopy	Safe during pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Magnetic resonance imaging	Not contraindicated at any gestation	
Computed tomography	Can be performed at any gestation	Radiation exposure to fetus and mother must be considered and addressed in counselling
Chest X-ray	Safe at any gestation	
Ultrasound	Safe at any gestation	
Echocardiogram	Safe at any gestation	
Ambulatory electrocardiogram	Safe at any gestation	

*For any investigation, the potential benefit must outweigh the risk.

pulmonary embolism, haemorrhage and amniotic fluid embolism (AFE). This usually presents with collapse and profound shock during delivery or immediately afterwards, often accompanied by a severe coagulopathy. It can be difficult to differentiate AFE from other causes of maternal collapse, and the diagnosis is often made on clinical grounds when other causes of collapse have been excluded. Management is supportive, with oxygenation, careful fluid balance and correction of coagulopathies where necessary, ventilatory support and vasopressors.

Another important cause of circulatory collapse is obstetric haemorrhage, which can be divided into ante-partum and post-partum subtypes. Ante-partum haemorrhage is defined as bleeding from the vagina after 24 weeks' gestation. Primary post-partum haemorrhage is defined as occurring in the first 24 hours after delivery, and secondary post-partum haemorrhage after 24 hours. Haemorrhage may be concealed, and physiological changes such as hypotension, tachycardia and tachypnoea may be late signs. Management is supportive with administration of blood, intravenous fluids and oxygen. Patients with post-partum haemorrhage may also benefit from uterotonic agents such as oxytocin. If the bleeding fails to settle, surgical intervention or interventional radiology may be required.

Headache

Migraine and tension headache may occur during pregnancy and should be assessed along the usual lines, as described in Chapter 27. Important causes of headache that are specific to pregnancy are pre-eclampsia, which should be suspected in patients with hypertension, oedema and proteinuria, and cerebral venous thrombosis, which should be suspected when there is a neurological deficit or seizures.

Nausea and vomiting

Nausea and vomiting are common during the first trimester of pregnancy and do not usually require any specific investigation or treatment. Other causes of nausea and vomiting are summarised in Box 30.4. Severe vomiting with significant weight loss and/or electrolyte disturbance suggests hyperemesis gravidarum, which is discussed in more detail later in this chapter.

Oedema

A mild degree of ankle oedema can occur in normal pregnancy, but significant oedema raises suspicion of pre-eclampsia, and this should be considered in patients who are also hypertensive and those with proteinuria (Fig. 30.2).

i 30.4 Differential diagnosis of severe nausea and vomiting in pregnancy

Gastrointestinal

- Peptic ulcer disease
- Gastroenteritis
- Appendicitis
- Pancreatitis

Endocrine and metabolic

- Thyrotoxicosis
- Addison disease
- Hyperparathyroidism
- Diabetic ketoacidosis

Neurological

- Space-occupying lesion
- Migraine

Pregnancy-associated conditions

- Hydatidiform mole
- Acute fatty liver of pregnancy
- Hyperemesis gravidarum

Genitourinary

- Urinary tract infection

Psychological

- Bulimia nervosa

Cardiovascular

- Myocardial infarction

Seizures

The causes and management of seizures during pregnancy are summarised in Box 30.5. An important cause is eclampsia, which should be borne in mind in patients with no previous history of seizures and accompanying features such as hypertension, oedema and proteinuria. Seizures can also occur secondary to electrolyte disturbances associated with hyperemesis gravidarum or hypoglycaemia. Other disorders that are more common during pregnancy and can present with seizures include cerebral venous thrombosis and thrombotic thrombocytopenic purpura (TTP).

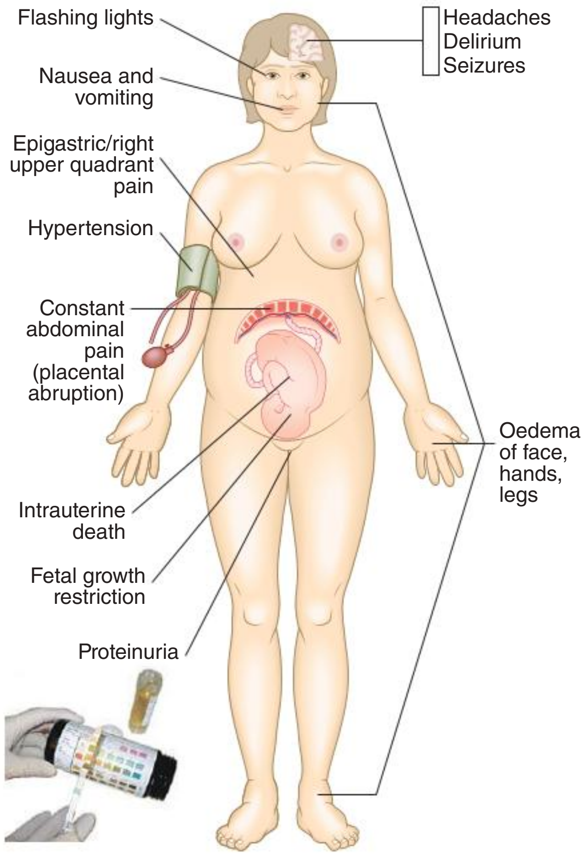

Fig. 30.2 Symptoms and signs of pre-eclampsia.

i 30.5 Causes of seizures during pregnancy

Cause	Management
Epilepsy	Similar to that in non-pregnant women Avoid valproate
Eclampsia	Antihypertensives Magnesium sulphate Careful fluid balance
Hypoglycaemia	Glucose
Hyponatraemia	Saline infusion
Alcohol withdrawal	Supportive treatment
Drugs	Supportive treatment
Stroke	As in non-pregnant women
Cerebral venous thrombosis	Low-molecular-weight heparin
Thrombotic thrombocytopenic purpura	Plasma exchange Immunosuppressives

Medical disorders in pregnancy

Many disorders present specific management problems before pregnancy, during pregnancy and in the puerperium; the most important of these are discussed in more detail below.

Hypertension

Hypertension is one of the most common medical problems during pregnancy, occurring in about 10%–15% of women. The causes and classification are summarised in Box 30.6.

Chronic hypertension

If hypertension is discovered during the first half of pregnancy, it usually indicates that there was pre-existing or chronic hypertension. This is most likely to be due to primary hypertension but secondary causes also need to be considered. Hypertension during pregnancy should be managed with vasodilators or methyldopa (Box 30.7), taking care to avoid hypotension. Angiotensin-converting enzyme (ACE) inhibitors should be stopped in hypertensive women who are planning to become pregnant and should be avoided during pregnancy since they have fetotoxic effects. Diuretics should also be avoided unless there is heart failure, as they can reduce circulating volume and cause placental hypoperfusion.

Gestational hypertension

Gestational hypertension usually presents in the second half of pregnancy and most often resolves by 3 months post-partum. It should be managed actively with one of the drugs listed in Box 30.7, to reduce the risk of progression to pre-eclampsia.

30.6 Classification of hypertension during pregnancy

Hypertension	Definition
Hypertension in pregnancy	Blood pressure $\geq$ 140/90 mmHg on two separate occasions, at least 4 hours apart
Chronic hypertension	Hypertension prior to pregnancy or occurring before 20 weeks' gestation
Gestational hypertension	Hypertension occurring after 20 weeks' gestation without proteinuria or any other features of pre-eclampsia
Pre-eclampsia	Hypertension occurring after 20 weeks' gestation with proteinuria, maternal organ dysfunction or uteroplacental dysfunction
Eclampsia	Generalised seizures in a pregnant woman with pre-eclampsia
White coat hypertension	Hypertension that only occurs in a clinical environment

Adapted from Magee L, Brown M, Hall D, et al. The 2021 International Society for the Study of Hypertension in Pregnancy classification, diagnosis & management recommendations for international practice. Pregnancy Hypertens 2022;27:148–169.

30.7 Drug treatment of hypertension during pregnancy

Medication	Dosage
Labetalol	100 mg twice daily to 600 mg 4 times a day
Nifedipine MR	10 mg twice daily to 40 mg twice daily
Amlodipine	5 mg to 10 mg once daily
Methyldopa	250 mg twice daily to 1000 mg 3 times a day
Doxazosin	0.5 mg twice daily to 8 mg 3 times a day

(MR = modified release)

Pre-eclampsia and eclampsia

Pre-eclampsia is a disorder of vascular endothelial dysfunction that affects about 10% of all pregnancies worldwide. The risk factors for pre-eclampsia are shown in Box 30.8 and the clinical features illustrated in Figure 30.2. Placental growth factor (PlGF) testing can be helpful in ruling out pre-eclampsia at pre-term gestations in women with suggestive symptoms.

Management includes control of blood pressure, administration of magnesium sulphate as prophylaxis against seizures, correction of coagulation abnormalities and monitoring of fluid balance. If pre-eclampsia occurs early in pregnancy, medical management should be initiated with the aim of controlling the condition and maintaining the fetus in utero as long as possible. If these measures are ineffective and eclampsia supervenes (see below), then urgent delivery should be considered, provided the fetus is viable, since this results in an immediate cure.

Eclampsia occurs in about 1% of pregnancies and is associated with significant mortality. It usually presents with seizures on a background of pre-eclampsia but rarely can occur before the onset of hypertension and proteinuria. Treatment is with intravenous magnesium sulphate 4 g intravenously over 15 minutes followed by an infusion of 1 g/hr titrated to serum magnesium for 24 hours, and delivery of the fetus as soon as possible. Women with pre-eclampsia are more likely to develop hypertension, chronic kidney disease, and cerebrovascular and ischaemic heart disease in later life.

Respiratory disease

Asthma

Women with asthma should be managed aggressively during pregnancy, since poorly controlled asthma is associated with pre-eclampsia, fetal growth restriction, low birth weight and pre-term birth. The management is very similar to that in non-pregnant individuals. Short-acting and long-acting β-agonists, inhaled and oral glucocorticoids, intravenous magnesium and theophylline can be used freely. Biologic agents such as the monoclonal anti-IgE antibody omalizumab can be given for severe allergic asthma, anti-IL-5 drugs such as mepolizumab for eosinophilic asthma, and the anti-IL-4/13 drug, dupilumab, for allergic and eosinophilic asthma. Leukotriene receptor antagonists can be continued during pregnancy. It is advisable to involve an anaesthetist or intensivist at an early stage in patients with severe exacerbations of asthma since airway management is more difficult in late pregnancy.

Respiratory infection

The most common causes of pneumonia during pregnancy are summarised in Box 30.9. Diagnosis and management are broadly the same as in non-pregnant patients. Prompt treatment of infections is important

30.8 Risk factors for pre-eclampsia

- Previous history of pre-eclampsia
- Multiple pregnancy
- Primiparity
- Genetic predisposition
- Obesity
- Increased maternal age
- Pre-existing medical conditions:
  - Chronic kidney disease
  - Hypertension
  - Diabetes mellitus
  - Systemic lupus erythematosus and connective tissue disease

Adapted from Duckitt K, Harrington D. Risk factors for pre-eclampsia at antenatal booking: systematic review of controlled studies. BMJ 2005;330:565–567.

30.9 Causes of pneumonia during pregnancy

Bacterial	
Streptococcus pneumoniae	*Haemophilus influenzae*
Mycoplasma pneumoniae	*Staphylococcus aureus*
Legionella	
Viral	
Influenza viruses	Varicella zoster

Adapted from Lim W, Macfarlane J, Colthorpe C. Pneumonia in pregnancy. Thorax 2001;56:398–405.

since mothers with pneumonia are more likely to deliver early and have low-birth-weight infants compared with healthy pregnant women.

Bacterial infections

Antibiotics should be given, depending on the causal organism and sensitivities, along with supplemental oxygen and fluids as required. Penicillins, cephalosporins and macrolides such as erythromycin are all safe during pregnancy but tetracyclines should be avoided because they may be fetotoxic and can cause staining of the teeth in the fetus (see Box 7.21).

Viral infections

Viral pneumonia is more common and often more severe during pregnancy. Varicella zoster pneumonia in particular is associated with a high fetal and maternal mortality rate. It presents with cough, breathlessness and pyrexia, and is usually preceded by a vesicular rash up to 1 week before. Varicella infection can be diagnosed clinically, with laboratory confirmation by culture or polymerase chain reaction (PCR) of fluid from vesicles, or by serology. Varicella pneumonia causes an interstitial pneumonitis with a characteristic nodular appearance on chest X-ray (p. 1300). Women with confirmed varicella zoster pneumonia should be admitted to hospital for supportive care and treatment with intravenous aciclovir for 7–10 days.

Tuberculosis

Tuberculosis (TB) may occur during pregnancy and in the UK is more common among African and Asian women. Untreated TB is associated with premature delivery and low birth weight. Transmission to the fetus can occur but is unusual. If the diagnosis of TB is confirmed, then antituberculous chemotherapy should be given as normal, and the neonate should receive bCG vaccination. A proportion of pregnant women with TB have coexisting human immunodeficiency virus (HIV) infection, which confers a poorer prognosis and requires treatment with antiretroviral therapy, as described in Chapter 14.

COVID-19

Pregnant women are not disproportionately affected by COVID-19, and should this occur during pregnancy, the same principles of treatment should be followed as for the non-pregnant population.

Gastrointestinal disease

Hyperemesis gravidarum

Hyperemesis gravidarum is a serious condition that affects about 0.5% of pregnant women. It typically presents during the first trimester with severe nausea, vomiting and other clinical features (Box 30.10). It is associated with significant morbidity and mortality due to malnutrition and electrolyte imbalance. Wernicke encephalopathy may develop as the result of thiamin deficiency. Recurrence is common in successive pregnancies. The cause is unknown, and the diagnosis is one of exclusion, since alternative causes of severe nausea and vomiting need to be ruled out, particularly if the onset of symptoms occurs after the first trimester. Management is with lifestyle advice and support, intravenous fluids, electrolyte replacement and antiemetics. Thiamin and glucocorticoids may be required in the most severe cases.

30.10 Clinical features of hyperemesis gravidarum

- Weight loss of > 5%
- Severe nausea and vomiting
- Electrolyte imbalance:
  - Hyponatraemia
  - Hypokalaemia
  - Hypomagnesaemia
- Dehydration
- Ketosis

Inflammatory bowel disease

Women with inflammatory bowel disease (IBD) should be counselled prior to planning a pregnancy. Medications such as azathioprine, sulfasalazine, 5-aminosalicylic acid (5-ASA), glucocorticoids and tumour necrosis factor alpha (TNF-α) inhibitors can be continued as normal during pregnancy, but methotrexate must be stopped at least 1 month before conception because of its teratogenic effects. Since poorly controlled IBD is associated with an increased risk of pre-term birth, low birth weight and miscarriage, it is important for the disease to be well controlled before conception. The activity of IBD can increase during pregnancy and ulcerative colitis is more likely to flare than Crohn disease. Women who experience disease flares should be managed by multidisciplinary teams including medicine and obstetrics and be monitored closely. Sometimes TNF-α inhibitors are stopped in the third trimester because most agents in this class are actively transported across the placenta, potentially causing immunosuppression in the neonate; however, if there is a significant risk of flare, TNF-α inhibitors should be continued. The TNF-α inhibitor certolizumab pegol, is a good choice since it does not cross the placenta in significant amounts throughout pregnancy. Most women with uncomplicated IBD can have a normal vaginal delivery and do not need a caesarean section, but the need for this should be assessed on an individual basis by obstetric and medical teams. See rheumatoid arthritis section for neonatal vaccine recommendations.

Diabetes

It is important to institute meticulous glucose control in pregnancy, as maternal diabetes is associated with increased risks of congenital malformations, stillbirth, pre-eclampsia, pre-term delivery, operative delivery, neonatal hypoglycaemia and admission to neonatal intensive care.

Gestational diabetes

Gestational diabetes is defined as diabetes with first onset or recognition during pregnancy. This definition will include a few patients who develop type 1 diabetes during pregnancy, where prompt action and early insulin treatment will be required, and some patients who develop type 2 diabetes, or had unknown pre-existing type 2 diabetes, in whom the diabetes does not remit after pregnancy. However, in most cases, gestational diabetes develops due to an inability to increase insulin secretion adequately to compensate for pregnancy-induced insulin resistance, and most women can expect to return to normal glucose tolerance immediately after pregnancy. Risk factors for gestational diabetes are shown in Box 30.11.

The diagnosis of gestational diabetes is based on maternal blood glucose measurements that are associated with increased fetal growth. An international consensus recommended that glucose values diagnostic of gestational diabetes should be lower than those for non-gestational diabetes (Box 30.12). Controversy remains about who should be screened, and the screening strategy depends, in part, on the population risk. It is widely accepted that women at high risk for gestational diabetes should have an oral glucose tolerance test at 24–28 weeks, and some guidelines recommend that all high-risk women should be screened by measuring

30.11 Risk factors for gestational diabetes

- Body mass index > 30 kg/m^2
- Previous macrosomic baby weighing ≥ 4.5 kg
- Previous gestational diabetes
- Family history of diabetes (first-degree relative with diabetes)
- Family origin with a high prevalence of diabetes:
  South Asian (specifically women whose country of family origin is Bangladesh, India or Pakistan)
  Afro-Caribbean
  Middle Eastern

30.12 Diagnosis of gestational diabetes

- Fasting plasma glucose of ≥ 5.1 mmol/L (92 mg/dL)
- 1 hour plasma glucose ≥ 10 mmol/L (180 mg/dL) after a 75 g glucose load
- 2 hour plasma glucose ≥ 8.5 mmol/L (153 mg/dL) after a 75 g glucose load

HbA$_{1c}$, fasting blood glucose or random blood glucose at the first booking visit. It should be noted that measurements of HbA$_{1c}$ cannot reliably be used to diagnose diabetes in early pregnancy and until 3 months post-partum, since HbA$_{1c}$ levels fall due to increased red cell turnover.

Management

The aim is to normalise maternal blood glucose concentrations and reduce the risk of excessive fetal growth. The first element of management is dietary modification, in particular by reducing consumption of refined carbohydrate. Women with gestational diabetes should undertake regular pre- and post-prandial self-monitoring of blood glucose, aiming for pre-meal blood glucose levels of < 5.3 mmol/L (96 mg/dL) and a 1-hour post-prandial level of < 7.8 mmol/L (142 mg/dL) or a 2-hour post-prandial level of < 6.4 mmol/L (109 mg/dL). If pharmacological treatment is necessary, metformin, glibenclamide or insulin can all be used. Glibenclamide should be used rather than other sulphonylureas because it does not cross the placenta. Other oral therapies or injectable incretin-based therapies should not be given in pregnancy.

After delivery, maternal glucose usually returns to pre-pregnancy levels. In the UK, it is currently recommended that women with gestational diabetes should have a fasting blood glucose measured at 6 weeks post-partum and have HbA$_{1c}$ concentrations measured annually to screen for the development of diabetes. This is because even those whose glucose tolerance returns to normal post-partum are at increased risk for developing type 2 diabetes, with a 5-year risk between 15% and 50%, depending on the population. Therefore, all women who have had gestational diabetes should be given diet and lifestyle advice to reduce their risk of developing type 2 diabetes later in life.

Pregnancy in women with established diabetes

Maternal hyperglycaemia early in pregnancy (during the first 6 weeks post-conception) can adversely affect fetal development, causing cardiac, renal and skeletal malformations, of which the caudal regression syndrome (abnormal development of the lower part of the spine) is the most characteristic. The risk of fetal abnormalities is about 2% for non-diabetic women and about 4% for women with well-controlled diabetes (HbA$_{1c}$ < 53 mmol/mol) but more than 20% for those with poor glycaemic control (HbA$_{1c}$ > 97 mmol/mol). Therefore, it is important for women with diabetes to aim to achieve good glycaemic control before becoming pregnant. In addition, high-dose folic acid (5 mg daily, rather than the usual 400 μg) should be initiated before conception to reduce the risk of neural tube defects.

As for gestational diabetes, mothers should attempt to maintain near-normal blood glucose levels while avoiding hypoglycaemia throughout their pregnancy, as this minimises excessive fetal growth and neonatal hypoglycaemia. This is often difficult to achieve, however. Pregnancy is also associated with an increased risk of ketosis, particularly, but not exclusively, in women with type 1 diabetes. Ketoacidosis during pregnancy is dangerous for the mother and is associated with a high rate (10%–35%) of fetal mortality.

Pregnancy is linked with a worsening of diabetic complications, most notably retinopathy and nephropathy, so careful monitoring of eyes and kidneys is required throughout pregnancy. If heavy proteinuria and/or renal dysfunction exist prior to pregnancy, there is a marked increase in the risk of pre-eclampsia, and renal function can deteriorate irreversibly during pregnancy. These risks need to be carefully discussed before a woman with diabetes is considering pregnancy. The outlook for mother and child has been vastly improved over recent years but pregnancy outcomes are still not equivalent to those of non-diabetic mothers. Perinatal mortality rates remain 3–4 times those of the non-diabetic population (at around 30–40 per 1000 pregnancies) and the rate of congenital malformation is increased five- to sixfold.

Endocrine disease

Thyroid disease

Iodine deficiency

Iodine deficiency is a major public health issue in many countries, particularly in South-east Asia, the Western Pacific and Central Africa. Severe iodine deficiency in pregnancy is associated with miscarriage, stillbirth and cretinism, with significant cognitive impairment, gait abnormalities and deafness in the affected child. More moderate iodine deficiency is associated with milder forms of cognitive impairment and affects millions of people. The World Health Organization recommends a daily iodine intake of 250 μg/day for pregnant women. Treatment of iodine deficiency in the first and second trimesters can prevent impaired cognitive development but is less effective if started in the third trimester.

Hypothyroidism

Hypothyroidism occasionally presents during pregnancy, with symptoms such as constipation, lethargy and weight gain, though more commonly women with hypothyroidism are already diagnosed before they become pregnant. The diagnosis is easily missed since these symptoms are common in normal pregnancy. If suspected, the diagnosis can be confirmed by checking thyroid function tests, which show a raised TSH and low free T4. The reference range for thyroid function tests is different in pregnancy, and results should be checked using a local gestation-specific reference range.

Women with hypothyroidism should aim for optimal disease control before conceiving, and throughout the pregnancy. Untreated hypothyroidism is associated with anaemia, miscarriage and pre-eclampsia. During pregnancy, women should have their thyroid function checked every trimester and dose adjustments made depending on the results, and blood tests repeated 4–6 weeks after any alterations. Some women may require an increase in their thyroxine dose during pregnancy to maintain normal TSH levels, because there is an increased requirement for thyroxine during pregnancy. TSH should be < 2.5 mIU/L for women on treatment prior to pregnancy.

Subclinical hypothyroidism is more common. There is no evidence that treating women with subclinical hypothyroidism and negative thyroid peroxidase (TPO) antibodies is beneficial. For TPO antibody–positive women, there are some data to suggest treating TSH above the upper limit of the reference range, but less than 10 mIU/L may be beneficial for pregnancy outcome.

Hyperthyroidism

The coexistence of pregnancy and thyrotoxicosis is unusual, since anovulatory cycles are common in thyrotoxic patients and autoimmune disease tends to remit during pregnancy, due to suppression of the maternal immune response. Thyroid function tests must be interpreted in the knowledge that thyroid-binding globulin, and hence total T4 and T3 levels, is increased in pregnancy and that the normal range for TSH is lower (see Box 33.10). Despite this, a fully suppressed TSH is usually indicative of Graves disease. When thyroid disease during pregnancy is being dealt with, both mother and fetus must be considered, since maternal thyroid hormones, TSH receptor antibodies (TRAb) and antithyroid drugs can all cross the placenta to some degree, exposing the fetus to the risks of thyrotoxicosis, iatrogenic hypothyroidism and goitre. Moreover, poorly controlled thyrotoxicosis can result in fetal tachycardia, intrauterine growth retardation, prematurity, stillbirth and possibly even congenital malformations.

Antithyroid drugs are the first treatment of choice for thyrotoxicosis in pregnancy. Newly diagnosed hyperthyroidism during pregnancy can be treated with β-adrenoceptor antagonists (β-blockers) in the short term, followed by antithyroid drugs. Propylthiouracil (PTU) is the preferred antithyroid drug because treatment with carbimazole during the first trimester has been associated with the occurrence of choanal atresia and aplasia cutis. Hyperthyroid women who become pregnant while taking carbimazole or PTU should be advised to continue their current drug in pregnancy, with close monitoring. Both carbimazole and PTU cross the placenta and are effective in treating thyrotoxicosis in the fetus caused by transplacental passage of TRAb. To avoid fetal hypothyroidism, which can affect brain development and cause goitre, it is important to use the smallest dose of antithyroid drug (typically < 150 mg PTU or 15 mg carbimazole per day) that will maintain maternal free T4, T3 and TSH concentrations within their respective reference ranges. Thyroid surgery is sometimes necessary because of poor drug adherence, drug hypersensitivity or failure of medical treatment and is most safely performed during the second trimester. Radioactive iodine is absolutely contraindicated throughout pregnancy, as it invariably induces fetal hypothyroidism. Frequent review of mother and fetus (monitoring heart rate and growth) is important during pregnancy and in the puerperium. Serum TRAb levels can be measured in the third trimester to predict the likelihood of neonatal thyrotoxicosis. PTU is the drug of choice in the breastfeeding mother, as it is excreted in the milk to a much lesser extent than carbimazole. Thyroid function should be monitored periodically in the breastfed child.

Post-partum thyroiditis

Post-partum thyroiditis typically presents 3–4 months after delivery. It is discussed in more detail in Chapter 20.

Pituitary disease

Prolactinoma

Prolactinomas are the most common pituitary tumours in young women. Although fertility is reduced in patients with prolactinoma, pregnancies can occur and if this happens the tumour may enlarge as part of the physiological pituitary enlargement that takes place during normal pregnancy. Macroprolactinomas (≥ 10 mm) are at greater risk of enlarging and may cause optic chiasm compression. If women known to have a prolactinoma become pregnant, they should have visual field testing each trimester, followed by pituitary imaging by MRI if enlargement is suspected from changes in visual fields or from symptoms. Measurement of serum prolactin is generally not helpful, since levels increase as part of normal pregnancy. Dopamine receptor agonists such as cabergoline and bromocriptine should normally be stopped during pregnancy, but can be reintroduced if necessary in patients with an enlarging prolactinoma that is threatening the visual fields.

Diabetes insipidus

Women with pre-existing diabetes insipidus may find that their symptoms worsen in pregnancy due to placental production of vasopressinase, a protease that degrades vasopressin (antidiuretic hormone, ADH). Because of this, pregnant women with diabetes insipidus may need higher doses of desmopressin until delivery. The development of symptoms suggestive of diabetes insipidus, such as thirst and polyuria, during pregnancy should raise suspicion of acute fatty liver of pregnancy (AFLP), the syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) or pre-eclampsia, as all these conditions are also associated with decreased breakdown of vasopressinase by the liver.

Sheehan syndrome

This is a form of post-partum hypopituitarism caused by infarction of the pituitary, usually associated with hypotension from major post-partum haemorrhage. It can present with failure to establish lactation after birth, amenorrhoea or other features of hypopituitarism. The diagnosis can be confirmed by tests of pituitary function and treated with hormone replacement, as described in Chapter 20.

Parathyroid disease

Primary hyperparathyroidism

Primary hyperparathyroidism (PHPT) is uncommon in women of child-bearing age, but if pregnancy does occur in a patient with pre-existing PHPT, careful monitoring is required. Women with mild disease can be managed conservatively, but if serum calcium levels rise above 2.85 mmol/L (11.5 mg/dL), consideration should be given to parathyroidectomy, as fetal mortality is high (up to 40%) in patients with severe hypercalcaemia. If parathyroidectomy is required, it should ideally be performed during the second trimester. Anecdotal evidence suggests that the calcimimetic drug, cinacalcet, can be used for medical management of PHPT during pregnancy.

Familial hypocalciuric hypercalcaemia

Familial hypocalciuric hypercalcaemia (FHH) is a benign disorder caused by mutations in the calcium-sensing receptor, which is described in Chapter 20. Although FHH poses no risk for pregnant women, the hypercalcaemia can suppress PTH secretion in neonates that do not inherit the FHH mutation, resulting in severe hypocalcaemia. Infants of mothers with FHH should have their serum calcium levels monitored during the first few days of life; if hypocalcaemia is detected, intravenous calcium should be given.

Adrenal disease

Women with known adrenal insufficiency can continue their glucocorticoid and mineralocorticoid replacement during pregnancy as normal. Rarely, adrenal insufficiency can present for the first time during pregnancy. If this occurs, the diagnosis is challenging because total cortisol normally increases during pregnancy, and short Synacthen tests can be falsely normal. Specialist assessment is required. In women with Conn syndrome who become pregnant, amiloride should be substituted for spironolactone to prevent anti-androgenic effects on a male fetus.

Human immunodeficiency virus infection

The course of HIV disease is not altered by pregnancy, but treatment with antiretroviral therapy should be given during pregnancy to women who are HIV-positive, as outlined in Chapter 14. In some societies, routine HIV testing is recommended at an early stage in pregnancy in all women.

Inflammatory rheumatic disease

Most women with inflammatory rheumatic disorders have successful pregnancies, but it is critically important for them to be given pre-conception counselling, to review medication use, optimise disease control and make them aware of the risks that pregnancy might pose to their condition and vice versa.

Rheumatoid arthritis

Women with rheumatoid arthritis should have a medication review; JAK inhibitors leflunomide, methotrexate and mycophenolate are all disease-modifying antirheumatic drugs (DMARDs) that should be

30.13 Safety of antirheumatic drugs during pregnancy and breastfeeding

Drug	Safe during pregnancy	Safe during breastfeeding	Comment
Anti-CD20 antibodies, e.g. rituximab	Consider in severe disease	Yes	
Azathioprine	Yes	Yes	
Ciclosporin	Yes	Yes	Data on breastfeeding limited
Cyclophosphamide	No	No	
Glucocorticoids	Yes	Yes	A good short-term option for disease flares
Hydroxychloroquine	Yes	Yes	
Interleukin antagonists	Consider in severe disease	Yes, though data are lacking	
Janus activated kinase	No	No	Stop before planning pregnancy
Leflunomide	No	No	Stop 2 years before planning pregnancy
Methotrexate	No	No	Stop at least 1 month before planning pregnancy
Mycophenolate	No	No	Stop before planning pregnancy
Non-steroidal anti-inflammatory drugs (NSAIDs)	Yes (<20 weeks)	Yes	
Sulfasalazine	Yes	Yes	Co-prescribe with folic acid
Tacrolimus	Yes	Yes	
Tumour necrosis factor (TNF) inhibitors	Yes	Yes	Avoid live vaccines in the neonate for 6 months

Adapted from Russell MD, Dey M, Flint J, et al. British Society for Rheumatology guideline on prescribing drugs in pregnancy and breastfeeding: immunomodulatory anti-rheumatic drugs and corticosteroids. Rheumatology (Oxford) 2023;62(4):e48–e88.

stopped and an alternative substituted before conception if necessary (Box 30.13). Rheumatoid arthritis often improves during pregnancy, particularly in those who are negative for rheumatoid factor or anti-cyclic citrullinated peptide antibodies. There is an increased risk of pre-eclampsia, pre-term birth and small babies for women with active disease, emphasising the importance of maintaining disease control during pregnancy. Glucocorticoids, hydroxychloroquine, azathioprine and sulfasalazine can all be continued as normal but non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided after 20 weeks (see Box 30.13). Inhibitors of TNF-α are safe during pregnancy and can be continued if necessary to maintain control of the disease. Many TNF-α inhibitors are actively transported across the placenta and this can lead to immunosuppression in the neonate. Accordingly, infants of mothers who have been treated with TNF-α inhibitors during the second and third trimesters may not be given live vaccines and should be monitored closely for any signs of infection, particularly if treatment is continued into the third trimester. An exception is certolizumab pegol, which is a pegylated antibody that is not transported across the placenta, but this is only used infrequently in IBD. Experience with other biologic therapies such as ustekinumab and vedolizumab during pregnancy is increasing and clinical experience suggests that these drugs may be used until at least the third trimester. Disease flares are common in the post-partum period, regardless of serology, and this can pose a problem for breastfeeding and care of the infant. Glucocorticoids are a good short-term option to control such flares, pending reintroduction of other DMARDs that might have been stopped prior to pregnancy.

Systemic sclerosis

Pregnancy in women with diffuse cutaneous systemic sclerosis (dcSSc), those with pulmonary hypertension or renal involvement and those with disease of recent onset (<4 years) poses risks to mother and fetus. In milder forms of the disease, however, the prognosis is better (Box 30.14). Raynaud phenomenon often improves during pregnancy due to vasodilatation, but oesophageal symptoms may worsen. Renal crises are no more frequent during pregnancy, but if one occurs, ACE inhibitors should be given. Although these are normally contraindicated in pregnancy, the potential benefit in this situation outweighs the risk to the fetus. Glucocorticoids, which can be given to promote fetal lung maturation in premature babies, should be avoided in women with SSc where possible because they may provoke renal crisis.

30.14 Systemic sclerosis (SSc) and pregnancy

Subtype	Effect of disease on pregnancy
Limited cutaneous SSc (lcSSc)	Good prognosis Raynaud phenomenon may improve Oesophagitis may worsen
CREST syndrome (a subtype of lcSSc)	Good prognosis Raynaud phenomenon may improve Oesophagitis may worsen
Diffuse cutaneous SSc (dcSSc)	Increased risk of: Fetal growth restriction Low-birth-weight babies Maternal and fetal mortality Pre-eclampsia Pre-term delivery

(CREST = calcinosis, Raynaud phenomenon, oesophageal involvement, sclerodactyly and telangiectasia)

Systemic lupus erythematosus

Pregnancy in women with systemic lupus erythematosus (SLE) poses several risks to both mother and fetus, especially if there is renal involvement. There is an increased risk of pre-eclampsia, thrombosis, fetal growth restriction, pre-term delivery, miscarriage and fetal death. There is also a higher risk of lupus flare during the puerperium. Good control of disease is paramount, since women with SLE who conceive when their disease has been quiescent for at least 6 months are less likely to have complications than those who conceive when their disease has recently been active. It can be difficult to assess disease activity during pregnancy because symptoms such as fatigue, hair loss, joint pain and oedema, which occur in active SLE, are also common during normal pregnancies. The features in Box 30.15 can help differentiate between an SLE flare, normal pregnancy and pre-eclampsia.

30.15 Differential diagnosis of lupus flare during pregnancy

Clinical finding	Lupus flare	Pre-eclampsia	Normal pregnancy
Hypertension	Yes	Yes	No
Proteinuria	Yes	Yes	No
Red cells/casts in urine	Yes	No	No
Liver function tests	Normal	Abnormal	Normal
Anti-double-stranded DNA	Increase	Unchanged	Unchanged
C3 and C4	Low	Elevated or unchanged from baseline	Unchanged

All women with SLE should be tested for anti-Ro and anti-La antibodies, since they can cross the placenta and cause neonatal complete heart block or cutaneous lupus, respectively. Medications should be reviewed prior to pregnancy, to ensure they are safe, and an alternative substituted if necessary (see Box 30.13). The management of patients with antiphospholipid antibodies is described below.

Antiphospholipid syndrome

Primary antiphospholipid syndrome (APS) is associated with an increased risk of adverse pregnancy outcomes, including thrombosis, miscarriage, fetal death and pre-eclampsia. This applies to primary APS and that associated with connective tissue diseases such as SLE. During pregnancy, women with APS should be managed with low-dose aspirin in combination with low-molecular-weight heparin (LMWH).

Bone disease

Osteoporosis can rarely present for the first time during pregnancy. Typically, this is with either hip or back pain in the third trimester or puerperium due to fractured neck of femur or multiple vertebral fractures, respectively. The cause is unknown, but it has been speculated that in some cases this may be due to amplification of the bone loss that normally occurs during pregnancy in women who have pre-existing low bone density. In other women, known risk factors for osteoporosis may be identified, such as inflammatory disease or corticosteroids. Pregnancy-associated osteoporosis improves even without treatment but patients with severe disease may be left with chronic back pain due to vertebral deformity. Bisphosphonates and other osteoporosis treatments are often given empirically post-partum to increase bone density, but the effects on fracture outcomes are unclear. Another presentation is with a localised form of osteoporosis affecting the femoral head, which presents with hip pain. This is thought to be a manifestation of chronic regional pain syndrome (CRPS) type 1. The diagnosis can be confirmed by MRI scan, which shows bone marrow oedema at the affected site. Treatment is symptomatic and the condition usually resolves spontaneously post-partum.

Cardiac disease

Congenital heart disease

Women who have a history of surgically corrected congenital heart disease generally tolerate pregnancy well but are more likely to have babies with congenital heart disease and should be offered fetal cardiac scans. Acyanotic heart diseases, such as atrial septal defect, ventricular septal defect and patent ductus arteriosus, all have a good prognosis in pregnancy. Unrepaired cyanotic heart disease has a very poor prognosis in pregnancy, as does pulmonary arterial hypertension, regardless of the underlying cause. Women with mechanical heart valves require anticoagulation throughout pregnancy but their anticoagulation should be planned with consideration of substituting warfarin with LMWH and aspirin during the first trimester to reduce the risk of warfarin embryopathy. If necessary, warfarin can be used during pregnancy, particularly in the second and third trimesters.

Valvular heart disease

The physiological changes of pregnancy may also unmask previously undiagnosed valvular disease. Women with regurgitant lesions, such as mitral regurgitation and aortic regurgitation, tolerate pregnancy better than those with stenotic lesions. Mitral stenosis causes a reduction in blood flow from the left atrium to left ventricle in diastole, which worsens during pregnancy due to the increased heart rate and hypervolaemia. Those with moderate to severe mitral stenosis (valve area $< 1.5\,\text{cm}^2$) are at particular risk and may develop arrhythmias, tachycardia and pulmonary oedema. Most patients can be managed medically with β-blockers, LMWH and furosemide as necessary. Surgical intervention is indicated if there is continued haemodynamic compromise despite optimal medical management.

Myocardial infarction

Pregnancy increases the risk of myocardial infarction. Whilst atherosclerosis is the main cause in non-pregnant individuals, coronary artery dissection and coronary thrombosis secondary to the hypercoagulable state are more common causes during pregnancy. Management is similar to that of non-pregnant women, except that statins and glycoprotein IIb/IIIa inhibitors such as tirofiban should be avoided where possible. Clopidogrel can be given but should be stopped around the time of delivery to reduce the risk of uterine bleeding and to allow spinal anaesthesia to be used if necessary. There is little evidence regarding ticagrelor, an alternative antiplatelet drug, during pregnancy. Stenting can be performed, but bare-metal stents are preferred because drug-eluting stents require dual antiplatelet therapy that cannot be continued around the time of delivery.

Aortic dissection

Pregnancy is an independent risk factor for aortic dissection, and this should be considered when a woman presents with acute severe chest pain during pregnancy. The vast majority of cases in pregnancy are ‘type A’, involving the ascending aorta (see Fig. 16.71), and require careful control of hypertension, caesarean section to deliver the fetus and emergency surgery to treat the aneurysm.

Peripartum cardiomyopathy

Peripartum cardiomyopathy (PPCM) presents with heart failure secondary to left ventricular systolic dysfunction towards the end of pregnancy or in the months following delivery. It is a diagnosis of exclusion, made when other causes of heart failure have been ruled out. The cause is unknown, but PPCM is more prevalent in women who are older, multiparous, hypertensive and of Afro-Caribbean origin. It is treated by conventional medications for heart failure, including ACE inhibitors if necessary, and delivery of the baby. Many women recover within 3–6 months of diagnosis but the prognosis is variable. There is a significant chance of reduction in cardiac function in subsequent pregnancies.

Dilated cardiomyopathy

Dilated cardiomyopathy carries a poor prognosis if the pre-pregnancy ejection fraction is below 30% or if symptoms are in New York Heart Association classes III or IV. Management is as described for PPCM.

Renal disease

Renal tract infection

Pregnancy predisposes women to urinary tract infection. If asymptomatic bacteriuria is discovered during pregnancy, it should be treated promptly with antibiotics, to prevent ascending renal tract infection. Pyelonephritis is more common in pregnancy due to the physiological dilatation of the upper renal tract; if it does occur, it can trigger premature labour.

Acute kidney injury

Acute kidney injury (AKI) may occur during pregnancy or in the puerperium due to a variety of causes (Box 30.16). Women with AKI caused by pre-eclampsia are prone to pulmonary oedema. Particularly close attention to fluid balance is very important for these women. Intravenous fluid is rarely indicated for women with pre-eclampsia, and most will undergo a diuresis in the days following the diagnosis and the AKI will resolve. If there is a coexisting condition such as sepsis with associated hypotension, then intravenous fluids may be helpful. It is wise to enlist the assistance of critical care medicine specialists early for such patients.

In the post-partum period, AKI may occur as the result of post-partum haemorrhage or pre-eclampsia, and sometimes these occur in combination. Although pre-eclampsia resolves after delivery, AKI can be at its worst in the first few days post-partum, especially when exacerbated by obstetric haemorrhage.

Glomerular disease

Proteinuria caused by glomerular disease is usually exacerbated during pregnancy, and nephrotic syndrome may develop without any alteration in the underlying disease activity in individuals who had only slight proteinuria before pregnancy. This further increases the risk of venous thromboembolism, the leading cause of maternal deaths in higher-income countries.

Chronic kidney disease

Women with chronic kidney disease (CKD) are at increased risk of pre-eclampsia, fetal growth restriction, miscarriage, pre-eclampsia, preterm delivery and fetal death (Fig. 30.3). Pregnancy can also cause acceleration of maternal renal decline. The factors that influence pregnancy outcome for women with CKD are baseline renal function, hypertension, degree of proteinuria and the underlying cause of CKD. Women with CKD should have pre-pregnancy counselling, be closely monitored by a multidisciplinary team throughout pregnancy, and be given low-dose aspirin as prophylaxis against pre-eclampsia.

Kidney replacement therapy

Dialysis

Fertility is reduced among women receiving maintenance dialysis and there is increased risk of adverse pregnancy outcomes. Despite this, many women receiving dialysis have successful pregnancies. More intensive dialysis is recommended in pregnancy, and particular attention should be paid to addressing issues around anaemia, blood pressure and fluid balance.

Renal transplant recipients

Pregnancy should be delayed for a minimum of 12 months following renal transplantation, to allow the graft to stabilise, on minimum immunosuppressive drugs. The outcome is best for women with a well-functioning graft, with no proteinuria or hypertension. Women with renal

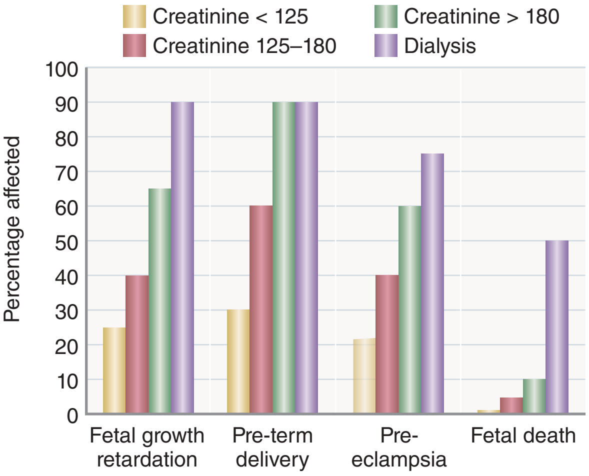

Fig. 30.3 **Adverse pregnancy outcomes in chronic kidney disease.** (Creatinine is in μmol/L. To convert to mg/dL, multiply by 0.011.) *Data from Williams D, Davison D. Chronic kidney disease in pregnancy. BMJ 2008;336:211–215.*

30.16 Causes of acute kidney injury in pregnancy

Mechanism	Cause	Features
Pre-renal	Hyperemesis gravidarum	Nausea and vomiting Dehydration Presentation in first trimester
	Post-partum haemorrhage	Vaginal bleeding
	Placental abruption	Abdominal pain or vaginal bleeding in second or third trimester
	Septic abortion	Presentation with hypotension, shock and pyrexia
Renal	Pre-eclampsia	Presentation in second and third trimesters with new-onset hypertension and proteinuria
	Thrombotic thrombocytopenic purpura	Possible antenatal or post-partum presentation with headache, irritability Haematology shows thrombocytopenia and microangiopathic haemolytic anaemia
	Acute fatty liver of pregnancy	Presentation with vomiting and abdominal pain in third trimester Abnormal liver function tests Liver ultrasound can be normal
	Acute interstitial nephritis	Most common cause is use of non-steroidal anti-inflammatory drugs
Post-renal	Acute urinary retention	Usual presentation is in third trimester due to enlarged uterus causing ureteric obstruction; sometimes presents post-partum

Adapted from Palma-Reis I, Vais A, Nelson-Piercy C, et al. Renal disease and hypertension in pregnancy. Clin Med 2014;13:57–62.

transplants can deliver vaginally, but in practice there is a higher incidence of caesarean section in this group, due to the higher incidence of pre-term delivery.

Liver disease

Specific causes of liver disease during pregnancy are discussed below.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare and serious condition that typically presents in the third trimester with vomiting, abdominal pain, jaundice and other symptoms (Box 30.17). It is more common in first pregnancies and multiple pregnancies and is associated with male fetuses. Rarely, fulminant liver failure may occur. The diagnosis can usually be made based on the clinical features, abnormal liver function tests (LFTs) and the appearances of fatty liver on ultrasound. A liver biopsy is rarely needed to make the diagnosis but shows microvascular steatosis. Management is with supportive care and by delivery of the fetus. The development of AFLP has been linked in some cases with an inherited deficiency of the enzyme long-chain acyl-CoA dehydrogenase (LCHAD) in the baby.

HELLP syndrome

The syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) is thought to be part of the spectrum of pre-eclampsia. It usually presents antenatally but can also appear for the first time in the postnatal period. The presenting symptoms can be the same as those of pre-eclampsia but can also include headache, right upper quadrant pain and visual disturbance. HELLP can be complicated by liver haematoma and capsular rupture. Management involves supportive care, control of hypertension, correction of coagulopathy and delivery of the fetus.

Obstetric cholestasis

Obstetric cholestasis is estimated to affect about 1% of pregnancies in women of European descent, although the prevalence is about 1.5% in women of Indian-Asian and Pakistani-Asian descent. The cause is incompletely understood but the condition is thought to be due in part to the cholestatic effect of high oestrogen levels. The typical presentation is in the third trimester with pruritus, particularly affecting the soles and palms. Laboratory testing reveals raised levels of bile acids and abnormal LFTs. The diagnosis can be made based on these clinical features when other causes of liver dysfunction and pruritus have been excluded. Treatment is with ursodeoxycholic acid (UDCA) at a starting dose of 250 mg twice daily, to improve symptoms and liver function. However, this treatment does not reduce the risk of adverse fetal outcomes. Rifampicin may be given as an additional therapy if UDCA is ineffective, and vitamin K should be given if clotting is abnormal. Aqueous cream with menthol can also be effective in soothing pruritus. There is an increased risk of fetal mortality with evidence of a particularly high risk when bile acid levels are over 100 µmol/L. Some centres induce labour before 40 weeks to reduce the risk. The risk of recurrence in future pregnancies is high.

30.17 Criteria for diagnosis of acute fatty liver of pregnancy

- Vomiting
- Abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin (> 14 µmol/L (> 0.82 mg/dL))
- Low glucose (< 4 mmol/L (< 72.4 mg/dL))
- Elevated urate (> 340 µmol/L (> 5.7 mg/dL))
- Leucocytosis ($> 11 \times 10^9$/L)
- Ascites or bright liver on ultrasound
- Elevated transaminases (alanine/aspartate aminotransferase (ALT/AST) > 42 U/L)
- Elevated ammonia (> 47 µmol/L (> 81.7 mg/dL))
- Renal impairment (creatinine > 150 µmol/L (> 1.7 mg/dL))
- Coagulopathy (prothrombin time > 14 secs or activated partial thromboplastin time > 34 secs)
- Microvascular steatosis on liver biopsy

Acute fatty liver of pregnancy can be diagnosed when ≥ 6 of the above features are present in the absence of another explanation.

Adapted from Ch'ng CL, Morgan M, Hainsworth I, et al. Prospective study of liver dysfunction in pregnancy in Southwest Wales. Gut 2002;51:876–880.

Viral hepatitis

The course of hepatitis B is unchanged in pregnancy, but it is important to identify women who have active infection to reduce the risk of vertical transmission to the fetus; this risk is up to 90% in women who are hepatitis B e-antigen-positive. Vaccinations and immunoglobulin should be given to infants of mothers who test positive for hepatitis B, and antiviral agents should be given to the mother after delivery. Vertical transmission rates of hepatitis C are low in the absence of HIV infection and so no action is required for the infant, unless there is co-infection with HIV; in this case, antiviral drugs should be considered. Pregnant women are at greater risk of contracting hepatitis E than the non-pregnant population. It is transferred via the faeco-oral route and is usually a mild self-limiting illness outside of pregnancy. However, it can cause fulminant hepatic failure in up to 20% of pregnant women.

Neurological disease

Epilepsy

Women with epilepsy should have pre-pregnancy counselling, should be advised to take high-dose folic acid from pre-conception, and should have their antiepileptic drugs (AEDs) reviewed. Many AEDs are associated with teratogenicity, and the risk increases with dose and use of multiple medications. Sodium valproate, in particular, is associated with a 40% risk of persistent neurodevelopmental disorders and a 10% risk of physical birth defects, which is considerably higher than for other AEDs. Ideally, sodium valproate should be avoided in women of child-bearing potential and an alternative AED substituted with a better safety profile, such as lamotrigine, levetiracetam or carbamazepine if it is safe to do so. The minimum number of drugs at the lowest effective dose required for control of epilepsy should be given, and women should be reminded of general safety advice, such as showering instead of bathing. Emergency management of seizures in a pregnant woman with epilepsy (without eclampsia) is the same as that in non-pregnant women. Whilst pregnancy does not generally affect the frequency of seizures in women with well-controlled epilepsy, those who enter pregnancy with poorly controlled epilepsy are likely to deteriorate. The plasma levels of some AEDs such as lamotrigine can fall in pregnancy. Seizures are more common at the time of delivery and women should be advised to deliver in a unit staffed with personnel able to manage this.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) may worsen during pregnancy due to weight gain. Treatment with acetazolamide can be continued during pregnancy but should be avoided in the first trimester due to lack of safety data. Therapeutic lumbar puncture can also be helpful. The mode of delivery is not affected by IIH, and spinal analgesia can be given as normal.

Migraine

Migraine often improves during pregnancy, but if attacks occur, they should be managed with simple analgesia and antiemetics. If necessary, prophylaxis can be given with aspirin, β-blockers or tricyclic antidepressants. Triptans can therefore be used for the treatment of migraine if other therapies are ineffective. Topiramate should be avoided.

Stroke

Stroke is twice as common in pregnant women as in non-pregnant women of the same age. The risk is highest during the third trimester and puerperium. The management of stroke during pregnancy is similar to that in non-pregnant patients. The risk of cerebral venous thrombosis is greatly increased during pregnancy. The presentation is with headache, seizures and neurological deficits such as hemiparesis. If the diagnosis is suspected, neuroimaging should be performed with MRI or CT venography. Management of acute infarct should be as for the non-pregnant patient and include consideration of thrombolysis.

Psychiatric disorders

Mood changes are common during pregnancy but more severe psychiatric disorders, such as depression or psychosis, typically present within 2–4 weeks of delivery (see Box 29.33). These disorders are discussed in more detail in Chapter 29.

Haematological disease

Anaemia

The causes of anaemia during pregnancy are summarised in Box 30.18. Iron deficiency anaemia is most commonly due to a 20% increased demand for iron. In most cases, it responds well to oral iron supplementation, with a rise in haemoglobin of approximately 0.8 g/L per week. If the haemoglobin does not rise following a 4-week trial of iron supplementation, alternative causes of anaemia should be considered. Non-adherence to oral iron is common and intravenous iron should be considered in women with iron deficiency and failure of oral treatment. It is generally not necessary to investigate iron deficiency anaemia during pregnancy unless there is clinical evidence of gastrointestinal blood loss, which should be investigated in the normal way.

Rhesus disease

Women who are negative for the Rhesus antigen should be offered treatment with anti-RhD immunoglobulin around the time of delivery to reduce the risk of haemolytic disease of the newborn. More details are provided in Chapter 24 and Box 24.19.

Thrombocytopenia

The causes of thrombocytopenia during pregnancy are summarised in Box 30.19. The most common cause is gestational thrombocytopenia, which typically occurs towards the end of pregnancy and resolves spontaneously after delivery. It is not associated with adverse pregnancy outcomes and requires no specific intervention. Pregnancy may occur in women with pre-existing idiopathic thrombocytopenic purpura (ITP). This should be managed with glucocorticoids and/or immunoglobulin, with the aim of maintaining the platelet count above 80×10^9/L at the time of delivery, in case spinal anaesthesia or caesarean section is required. Thrombocytopenia may also occur as a component of haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Both are characterised by microangiopathic haemolytic anaemia, acute kidney injury and thrombocytopenia, but in TTP neurological symptoms and fever also occur. These conditions are rare but important to recognise since up to one-quarter of cases occur during pregnancy and the post-partum period. TTP is managed with plasma exchange, fresh frozen plasma and sometimes glucocorticoids or rituximab. Platelet transfusion should be avoided.

i 30.18 Causes of anaemia in pregnancy

Microcytic

- Iron deficiency
- Haemoglobinopathies
- Thalassaemia

Normocytic

- Anaemia of chronic disease
- Haemorrhage
- Haemolysis

Macrocytic

- Vitamin B_{12}/folate deficiency
- Liver disease
- Alcohol excess

Venous thromboembolism

The risk of venous thromboembolism (VTE) is 4–5 times higher in pregnancy than in non-pregnant women. Women should receive risk assessments for VTE during their pregnancy, based on individualised risk factors (Box 30.20). Based on their personal level of risk, women will be given general advice such as ensuring adequate hydration and mobility, and those at higher risk will be advised to take daily LMWH during pregnancy and the post-partum period. It is a safe drug in pregnancy and does not cross the placenta. Deep venous thrombosis (DVT) is the most common presentation and more commonly affects the left leg in pregnancy. Treatment with LMWH should be started once the clinical suspicion has been raised (unless there is a strong contraindication), and diagnostic imaging sought. Measurement of D-dimer is not useful in pregnancy because levels rise as part of normal pregnancy, and clinical decision rules such as the Wells score are not validated for use in pregnancy. Doppler ultrasound scan is the investigation of choice. If the initial Doppler ultrasound scan is negative, and clinical suspicion low, treatment with LMWH can be stopped. However, if the clinical suspicion remains high, treatment can be stopped, and the scan repeated on day 3 and/or day 7. If proximal DVT is suspected, then an MRI of the abdomen should be considered.

Pulmonary embolism (PE) is a significant cause of death in pregnancy. It usually presents with symptoms such as breathlessness, pleuritic chest pain and haemoptysis, and signs such as tachypnoea, tachycardia, hypoxia and hypotension. Initial investigations should include an ECG, CXR and blood tests, including a troponin. Further details of investigations for possible PE are in the Imaging section earlier in this chapter. Treatment of PE in pregnancy is with LMWH at a higher dose than outside of pregnancy, based on the patient's weight. For women with massive PE, systemic or catheter-directed thrombolysis should be considered.

Women with a previous history of VTE who are receiving warfarin or direct oral anticoagulants as prophylaxis should have these stopped prior to conception and LMWH should be substituted. Women on treatment dose LMWH need careful planning around the time of delivery, to balance the need for anticoagulation against bleeding risk from epidural/spinal anaesthetic techniques, and delivery. LMWH and warfarin are both safe in breastfeeding. There is insufficient evidence regarding direct oral anticoagulants in breastfeeding, and they are considered unsafe.

i 30.19 Causes of thrombocytopenia during pregnancy

- Gestational thrombocytopenia
- HELLP (haemolysis, elevated liver enzymes and low platelets)
- Haemolytic uraemic syndrome
- Idiopathic thrombocytopenic purpura
- Systemic lupus erythematosus
- Thrombotic thrombocytopenic purpura

30.20 Risk factors for VTE in pregnancy

Pre-existing risk factors
Previous VTE Thrombophilia (inherited and acquired) Medical comorbidities, e.g. cancer, active IBD, active SLE, nephrotic syndrome Age > 35 years Obesity Smoking Gross varicose veins Parity ≥ 3
Obstetric risk factors
Multiple pregnancy Pre-eclampsia Prolonged labour > 24 hours Mid-cavity of rotational operative delivery Stillbirth Pre-term birth PPH
Transient risk factors
Surgery while pregnant Hyperemesis gravidarum Ovarian hyperstimulation syndrome Immobility Systemic infection Long-distance travel

(IBD = inflammatory bowel disease; PPH = post-partum haemorrhage; SLE = systemic lupus erythematosus; VTE = venous thromboembolism)
Adapted from RCOG Green-top Guideline 37a: Reducing the risk of venous thromboembolism during pregnancy and the puerperium, April 2015.

Multiple Choice Questions

30.1. A 32-year-old woman presents at 14 weeks' gestation to the emergency department, with dyspnoea and pleuritic chest pain. Her blood pressure (BP) is 70/40 mmHg, heart rate 140 beats/min, respiratory rate is 28 breaths per minute, oxygen saturations 85% on air, and temperature 36.5°C. She undergoes a CTPA scan, which reveals large bilateral pulmonary emboli, with evidence of right heart strain. Which of the following is correct?

A. The fetus should be delivered immediately to aid maternal resuscitation
B. She should be considered for systemic intravenous thrombolysis
C. The patient should be transferred to a specialist cardiothoracic centre
D. The patient should be counselled about direct oral anticoagulants (DOACs)
E. She should be advised against future pregnancy

Answer: B.

This woman has evidence of massive pulmonary emboli, and should be considered for systemic thrombolysis, which is not contraindicated in pregnancy. Delivering the fetus will not alter the resuscitation of this woman, because a fetus at 14 weeks will not cause IVC compression. In addition, this woman has not undergone a cardiac arrest, where a perimortem section is indicated in arrested patients at greater than 20 weeks' gestation. She does not require transfer, but instead needs urgent management at the hospital she presented to. DOACs are not currently considered safe in pregnancy, and would be inadequate to be the initial treatment for massive pulmonary emboli both inside and outside of pregnancy. Future pregnancy is a possibility, with planning and prophylactic low-molecular-weight heparin.

30.2. A 40-year-old woman presents at 30 weeks' gestation with a swollen left calf. She has a history of protein C deficiency and Crohn disease, which has been flaring in the last few weeks. She has been advised to take prophylactic low-molecular-weight heparin, but has struggled with administering the injections. A Doppler ultrasound scan of her left leg is negative. What is the most appropriate course of action?

A. Reassure her and discharge her
B. Demonstrate how to safely administer the injections
C. Admonish her for not taking the injections
D. Repeat the scan on day 3
E. Refer to haematology

Answer: D.

This woman is at high risk of VTE, and has not been receiving adequate prophylaxis. The scan should be repeated on day 3, because clinical suspicion remains high.

30.3. A 23-year-old woman undergoes delivery at 37 weeks' gestation, having been diagnosed with pre-eclampsia. She has an acute kidney injury (AKI), with a creatinine of 130 μmol/L. There are no other causes and she is euvolaemic. Which of the following is the most appropriate management?

A. Refer to nephrology for consideration of renal replacement therapy
B. Give 250 mL bolus of 0.9% saline, followed by 125 mL/hour and monitor fluid balance closely
C. Advise the patient to drink to thirst, and monitor fluid balance closely
D. Give 1000 mL bolus of Hartmann's solution, and monitor fluid balance closely
E. Start prednisolone 20 mg once daily, monitor fluid balance closely and repeat bloods daily

Answer: C.

In a euvolaemic patient with an AKI secondary to pre-eclampsia, it is highly likely that she will undergo a diuresis without intervention, and the AKI will resolve. Giving intravenous fluid puts the woman at risk of pulmonary oedema. There is no indication for steroids or renal replacement therapy.

30.4. A 27-year-old woman presents with pruritus at 32 weeks' gestation. She is diagnosed with obstetric cholestasis (intrahepatic cholestasis of pregnancy). Which of the following statements is true?

A. Her risk in subsequent pregnancies is increased
B. She should be started on ursodeoxycholic acid (UDCA) to reduce the risk of stillbirth
C. She is likely to need a caesarean section
D. Vitamin K is contraindicated, so international normalised ratio (INR) can be monitored
E. She should be admitted to hospital for observation

Answer: A.

Women with obstetric cholestasis (OC) are more likely to experience OC in future pregnancies. UDCA may improve her symptoms and liver function, but there is no evidence to show it improves fetal outcomes. There is no indication for caesarean section or admission based on the diagnosis alone and information given. Vitamin K should be given to women to correct coagulopathy.

30.5. A woman with known epilepsy experiences three generalised tonic–clonic seizures, from which she does not recover consciousness in between. She is 13 weeks pregnant and has protein ++ on her urine dip. What is the appropriate emergency drug treatment?

A. Intravenous (IV) magnesium sulphate
B. IV lorazepam
C. Buccal midazolam
D. IV phenytoin
E. Rectal diazepam

Answer: B.

This woman is in status epilepticus, and the initial treatment is with intravenous benzodiazepines. She is likely to need additional drugs to gain control of her seizures. IV magnesium is a treatment for eclamptic seizures, but at 13 weeks' gestation, it is too early in the pregnancy for eclampsia. The protein on her urine dipstick needs to be quantified with laboratory testing, and an explanation sought. Giving buccal therapies is inadvisable in patients with decreased conscious level. IV phenytoin may be needed as an additional therapy but is not the first or best choice in an emergency. Rectal therapies are not first-line treatment for status epilepticus.

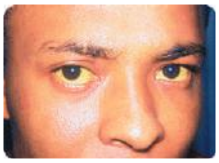
Summary 1335

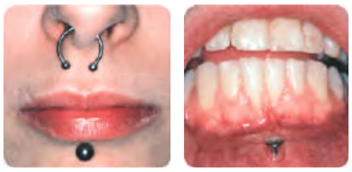
Comprehensive assessment of the young adult

5 Hepatic

Paracetamol overdose, tattoos and piercings, sexual contacts, alcohol use



Jaundiced sclerae in a young person



Piercings

4 Pancreatic

Type 1 diabetes and adherence

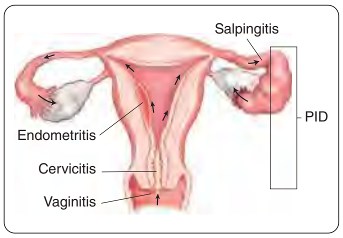
Obesity and type 2 diabetes

3 Renal

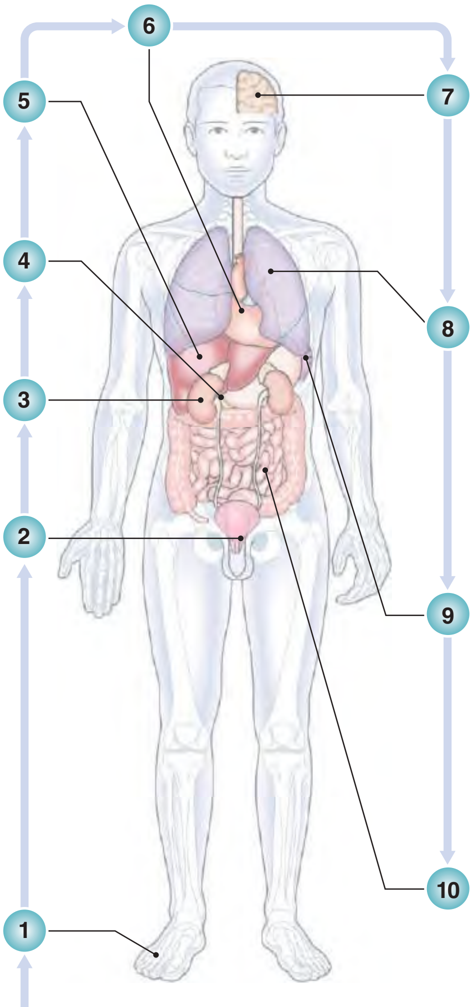
Perform urinalysis and BP
Family history of chronic kidney disease
Congenital urinary tract abnormality, Henoch–Schönlein purpura, transplant

2 Genitourinary/pelvic

Puberty, sexual health, endometriosis, Gender identity, risk of sexual exploitation

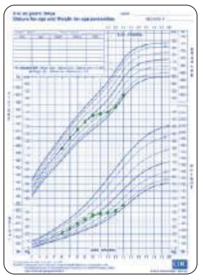


Features of pelvic inflammatory disease (PID)



1 Musculoskeletal

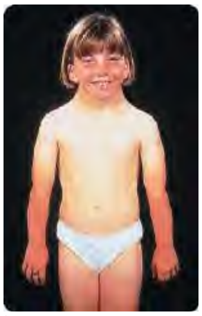
Impact of chronic ill health
- Arthropathy
- Arthritis
- Injury
- Osteogenesis imperfecta
- Eating disorder



Percentile chart for height and weight

6 Cardiac

Congenital heart disease syndromes
Palpitations/chest pain/syncope – common and often benign



Turner syndrome

7 Brain and neurodevelopmental

Psychosocial screening
Mood
Maturation and development

8 Respiratory

Smoking/vaping
Asthma plan adherence
Cystic fibrosis

Young person using a metered dose inhaler

9 Immune system function

Recurrent bacterial or viral infection (e.g. Epstein-Barr virus), malignancy, haemoglobinopathies

10 Gastrointestinal

Diarrhoea, constipation, pain, reflux, vomiting, weight loss (can be non-organic),

Young person with abdominal pain

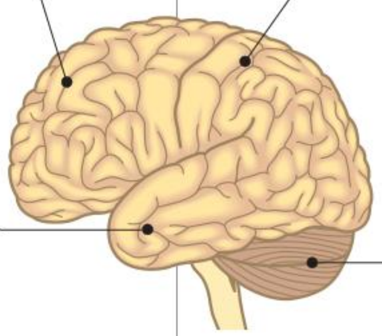
Development of the brain during adolescence



1 Pre-frontal cortex

Mini manager. Undergoes pruning in adolescence. Responsible for logic, decision-making, reasoning, complex thinking; immature in adolescence, grows until 25 years.

2 Amygdala

Emotional brain. Overrides the pre-frontal cortex in adolescence, such that adolescents' decisions are more likely to be governed by impulse, instincts, emotions, sensation-seeking and fight and flight responses.

3 Parietal lobe

Responsible for touch, sight, language. Grows until 25 years, language processing affected when not fully developed.

4 Hippocampus

Together with the amygdala forms the limbic system. Hub of memory and learning. Vital for storing memories and retrieving them to learn from. Grows in adolescence.

Psychosocial screening for adolescents and young adults – an aid to history-taking

It is best to have a semi-structured way to guide or direct a discussion with an adolescent patient seeking medical help, such that enquiry about lifestyle, behaviour and emotional well-being are interwoven into the medical history-taking.

The SSHADESS screening tool is an example of this. It focuses on a strengths-based approach which differs from the more traditional HEADSS screening tool. It begins with strengths to demonstrate the broader context of the young person's life and looks to minimise the focus on risk behaviours which may lead to feelings of shame.

Strengths

How would you describe yourself? What are you good at/what do you like doing?
How do you think your friends would describe you? What are you proud of?

School

What do you enjoy most/least about school? Do you get in trouble ever? What for?
How are your grades? Do you miss many days of school?

Home

Who lives at home with you? Do you feel safe at home?
Can you talk to anyone, or is there a family member that you go to more than others?

Activities

Do you trust your friends? Are they the same age or older?
What do you get up to after school/at weekends? What do you do for fun?

Drugs

Do any of your friends talk about smoking, vaping, drinking alcohol, taking drugs?
Do you?
How does it make you feel? What does it do for you?
Who do you drink/smoke/take drugs with? How do you pay for it?

Emotions, eating and depression

Have you been feeling stressed? How is your sleep?
Do people get on your nerves or wind you up more than they used to?
Do you often feel nervous/bored/agitated/sad?
Would you say that you eat healthily? Have you ever tried to gain or lose weight? Why?

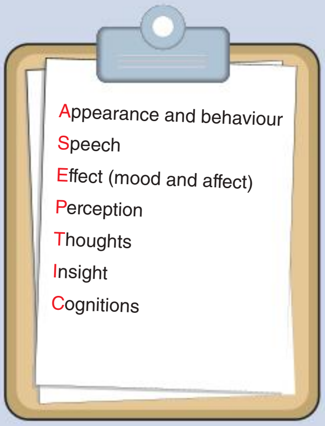
Sexuality

Are you in a relationship? Are you enjoying being together? Anything worry you?
Are you attracted to anyone? Tell me about that person? Are you into guys, girls, both?
Are many of your mates sexually active? You? How do you keep yourself safe?

Safety

Have you been bullied? Are there many bullies at school? Do you know anyone who carries a weapon?
Are you in control of how you use your phone and contacts in your phone?
Anyone you know display erratic behaviour or jealousy?
Do you ever see fights or witness people say mean things to each other at home/school?
Do you ever feel pressured to do things but would prefer not to?

ASEPTIC mnemonic: a structured assessment of mental capacity, mood and cognitive and behavioural functioning to establish state of mind



Appearance and behaviour
Speech
Effect (mood and affect)
Perception
Thoughts
Insight
Cognitions

Screening tool for an eating disorder – SCOFF

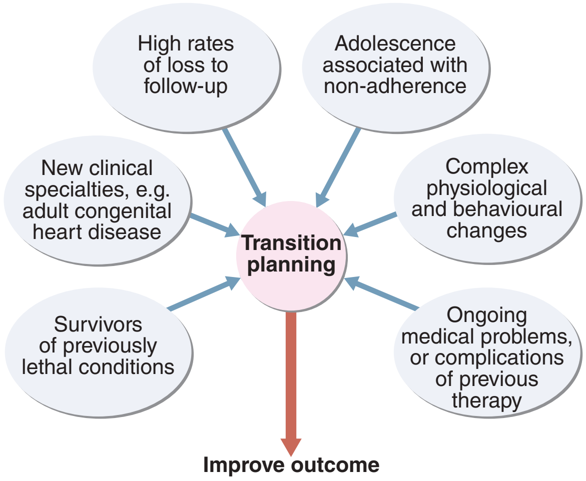
- Do you make yourself **S**ick because you feel uncomfortably full?
- Do you worry you have lost **C**ontrol over how much you eat?
- Have you recently lost more than **O**ne stone (6 kg) in a 3-month period?
- Do you believe yourself to be **F**at when others say that you are too thin?
- Would you say that **F**ood dominates your life?

Historically, childhood illnesses were characterised by a series of acute episodes, often infective, on a background of an otherwise healthy patient. Adult medicine traditionally comprised patients with progressive conditions and increasing pathology with advancing age. A number of factors have led to the recognition that boundaries between adult medicine and paediatric care are not clear-cut, and recent evidence has confirmed that anticipating and carefully planning the transition of children with long-term conditions (LTCs) into adult services improves care and outcomes. There is growing recognition that adolescence lasts up to age 25 years. Thus, transition for young people in medical services should be conducted ideally when developmentally appropriate and not at an arbitrary cut-off age of 16 years or 18 years, which are choices that suit service design rather than the young person and their family. Some services are beginning to configure themselves to accommodate up to age 25 years or indeed flexing to become an 'all age' service, but this approach does not lend itself easily to all medical specialties. An appropriate compromise is to attempt to ensure that transition occurs at a point of relative stability and that readiness for transfer of care is assessed holistically, to avoid a failed transition that may result in a poor experience or outcome. This might involve the need for paediatric services to 'hold on for a little longer', or indeed engage adult-focused services much earlier in the young person's journey.

Transition planning is often perceived as the responsibility of the team that the young person is leaving, but it is important to recognise that successful transition needs the receiving care team to show willingness to reach down and 'scoop up'. Involving non-medical professionals or voluntary sector workers such as youth workers to advocate for and support a young person on their transition journey can be highly successful in helping to bridge the gap.

About 14% of children in the industrialised world are diagnosed with a LTC, and in the majority of patients the disorder will persist into adulthood. Common illnesses include asthma, epilepsy, congenital heart disease, diabetes and childhood cancer (Box 31.1). In the last decade, and particularly since the COVID-19 pandemic, the profile of psychosocial dysfunction and functional pathology has climbed immeasurably in young people, representing an increasing workload for medical professionals and an increasing burden and challenge for patients. Similar trends are developing worldwide, with increasing survival rates of children with complex pathology and increasing prevalence of lifestyle-related conditions such as obesity, hypertension and type 2 diabetes. Specific factors that make transition planning important in young people with LTCs are outlined in Figure 31.1.

Planning the process of transition from paediatric to adult health services and improving the assessment of young people as they enter those adult services have been shown to impact positively on long-term health outcomes. There is a need for physicians to gain new skills in the care of young people and adults who have conditions that have arisen in childhood. This includes developing specific skills in the management of adolescents and young adults, managing the process of transition and developing knowledge of relevant medical conditions. The overall approach to transition medicine, as well as important disease-specific issues, will be considered in this chapter.



High rates of loss to follow-up
Adolescence associated with non-adherence
New clinical specialties, e.g. adult congenital heart disease
Complex physiological and behavioural changes
Transition planning
Survivors of previously lethal conditions
Ongoing medical problems, or complications of previous therapy
Improve outcome

• HIV/AIDS	• Malaria

Transition from paediatric to adult health services

Effectiveness of transition planning

A review of the effectiveness of transition planning has confirmed improved health outcomes when specific interventions to improve coordination between adult and paediatric services are implemented. Most research in this field has been undertaken with young people with diabetes, and many of the outcome measures relate to that condition. The principles of transition planning and the potential benefits are, however, likely to be generalisable to other LTCs that present in childhood. Young people with serious LTCs are among the most complex and high-risk patients to care for in adulthood, and it is important to work closely with them as they move to adult services, to try to improve their long-term outcome.

General principles of transition planning

Paediatric services are organised and delivered in a very different way to adult medical services. They encompass a period of life that spans from infancy to independence, and progress from taking parents' views as paramount to needing to recognise the wishes of the young person. After transition, young people move from medical services that have been family-centred and focused around maximising the child's development, to a service that encourages patient autonomy, in which employment and reproduction are important measures of outcome. At the same time as undergoing transition within medical services, young people are making multiple other transitions in their lives as they move from a dependent

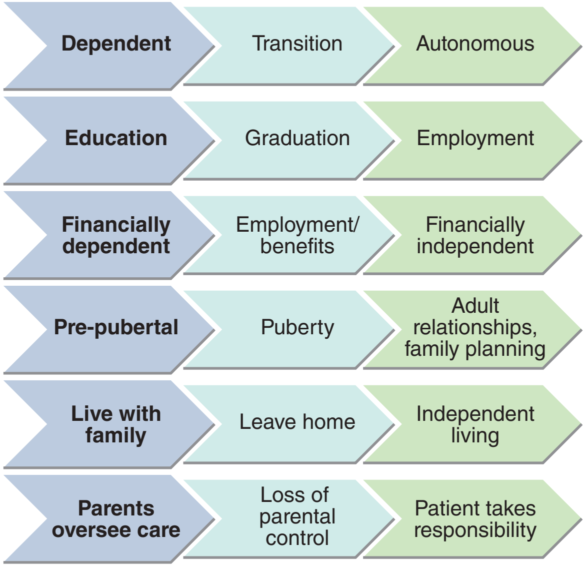

Fig. 31.2 Lifestyle changes during transition to adulthood.

to an independent way of living (Fig. 31.2). They often move away from the family home, and parents who formerly held responsibility for patient management, coordination of care, communication and consent to treatments will be demoted to an advisory role. Paediatric services are not well placed to meet this change in focus from the patient as a child to the patient as an independent adult, and young people benefit from the move to adult services as long as their specific needs as a young adult are recognised.

Principles of prescribing during transition

Hepatic drug metabolism increases from neonatal levels during childhood, eventually decreasing to adult levels after puberty. Once puberty has been completed, adolescents can be considered, in pharmacokinetic and pharmacodynamic terms, to behave like adults. It is important to remember that many young people have considerably lower body mass, and therefore body mass index (BMI), than adults, and care needs to be taken to avoid excessive dosage in physically smaller patients. Medicines are often prescribed on a dose per kilogram basis in children, to ensure that they are not exposed to inappropriately high drug concentrations. In young people who are obese (those in whom actual body weight is > 20% above their ideal weight), this can potentially lead to problems if the calculated dose per kilogram exceeds the standard adult dose. Accordingly, the ideal weight for the patient's height rather than actual body weight should be used to calculate drug dosages when prescribing for obese young people. This can be easily done in clinical practice using centile charts to calculate ideal body weight based on the patient's age and height. Whether or not the patient is obese, it is important not to exceed the recommended adult dose when prescribing for young people.

A systematic approach to transition planning

Several steps need to be undertaken to develop a successful programme for transition of care. The key components are summarised in Box 31.2. The first step is to establish a policy in consultation with young people and train staff in the policy. Subsequently, systems need to be developed to identify patients in need of transition and track them as they pass through the programme. Adult health-care providers need to be identified and processes developed for introducing the young person to the adult team. This should be followed by written communication between the paediatric and adult teams, and then a first consultation with the adult team at which the transfer can be reviewed and a care plan developed. There should subsequently be written communication between the adult and paediatric teams to confirm that handover has occurred, followed eventually by integration of the young person's care into the adult service.

31.2 Core elements in developing a transitional care programme

Establishing transition policy
- Develop policy, with input from young people
- Train staff in operation of policy

Tracking and monitoring
- Establish process to identify patients
- Develop systems to track individual progress
- Incorporate transition planning into clinical care

Transition readiness
- Identify suitable adult care provider
- Establish process for introduction to adult team
- Provide written information about joint first consultation

Transition planning
- Ensure communication between paediatric and adult teams
- Identify need for handover consultation
- Prepare written medical handover:
  - Diagnosis
  - Current treatment
  - Previous key issues
- Send relevant information in advance
- Provide information and community support

Transfer to adult services
- Arrange first consultation
- Review transfer package with team
- Identify concerns of young person
- Review young person's health priorities
- Update medical summary and emergency care plans

Integration into adult services
- Communicate with paediatrics and confirm transfer
- Help young adult to access other adult services
- Continue individualised care plan tailored to young person
- Seek feedback from young adult about transition

A number of organisations have published guidelines to planning transition services. Two of the best known include the 'Ready Steady Go' programme in the UK and the American Academy of Pediatrics' 'Got Transition' (see 'Further information'). Details of the sorts of competencies that a young person might need before making a full transition to adult medical services are outlined in Box 31.3.

When should transition happen?

The optimum timing for transition is not specifically defined; it is a process that evolves over a number of years, during which puberty and then adolescence occur. Transition should generally be initiated at around 12 years of age. Completion time then varies from person to person, also depending on the model of adult services available. Most commonly, full transition occurs between 16 and 18 years of age, which coincides with other areas where young people are considered to have made the transition to adulthood, such as the completion of formal education. Increasingly, services offer considerable flexibility about the upper age limit (Fig. 31.3).

Functional anatomy and physiology

Puberty and adolescence are developmental stages through which children progress during the second decade of life. During this phase, several physical, biochemical and emotional changes occur. The most important are discussed in more detail below.

Endocrine changes

The hormonal and physical stages of progression through puberty in males and females are summarised in Figure 31.4. Puberty is initiated by pulsatile increases in gonadotrophin-releasing hormone (GnRH) by the hypothalamus, which in turn stimulates pulsatile release of luteinising hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary. In males, the increased production of LH stimulates Leydig cells in the testes to produce testosterone, and FSH acts on Sertoli cells to stimulate sperm production, as described on page 709 and shown in Figure 20.14. The rise in testosterone increases skeletal growth, promotes development of the male genital organs and stimulates growth of pubic, facial and axillary hair. In females, FSH and LH act on the ovary to promote follicle production, ovulation and menstruation, as described on page 709 and shown in Figure 20.15. Other hormonal changes in all adolescents include a rise in adrenal androgens and a rise in growth hormone, which in turn stimulates production of insulin-like growth factors 1 and 2 (IGF-1 and IGF-2). Insulin production also rises by about 30% during puberty. These hormonal changes contribute to the biological, morphological and psychological changes seen during the teenage years. Adolescence (as opposed to puberty) comprises not only the physical changes of puberty, but also the wider emotional and psychological changes of progression into early adulthood. The emotional and psychological changes are associated with physical maturation but also with sociocultural influences. The feelings and behavioural development of normal adolescence are complex but tend to follow fairly predictable patterns.

i 31.3 Key features in assessing readiness for transition to adult services

(K) Knowledge

1. Describes condition, effects and prognosis
2. Understands medication purpose and effects
3. Understands treatment purposes and effects
4. Knows key team members and their roles

(S) Self-advocacy

1. Can attend part/whole clinic appointment on their own
2. Knows how to make appointments/alter appointments
3. Has understanding of confidentiality
4. Orders repeat prescriptions
5. Takes some/complete responsibility for medication/other treatment
6. Knows where to get help

(H) Health and lifestyle

1. Understands importance of diet/exercise/dental care
2. Understands impact of smoking/alcohol/substance use
3. Understands sexual health issues/pregnancy/sexually transmitted infections

(A) Activities of daily living

1. Self-care/meal preparation
2. Independent travel/mobility
3. Trips/overnight stays away from home
4. Benefits/financial independence

(V) Vocational

1. Current and future education/impact of condition on career plans
2. School attendance and performance
3. Work experience and access to careers advice
4. Outside activities and interests
5. Disclosure to school/employer

(P) Psychosocial

1. Self-esteem/self-confidence
2. Body/self-image
3. Peer relationships/bullying
4. Support networks/family/disclosure to friends
5. Coping strategies

(T) Transition

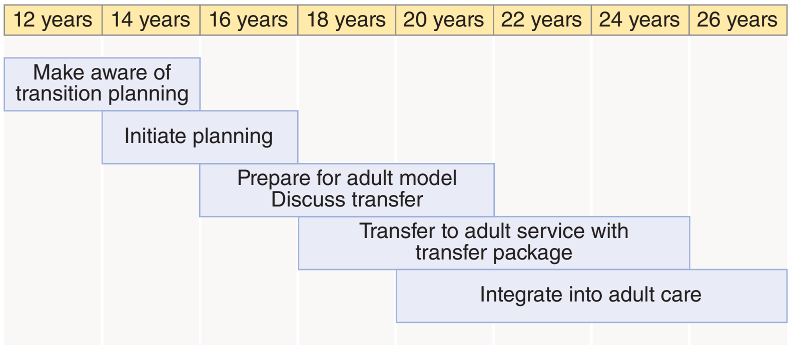
1. Understands concept of transition
2. Agrees transition plan
3. Attends transition clinic
4. Visits adult unit (if appropriate)
5. Sees primary care team/other clinical staff independently

Physical changes

In girls, there is an increased rate of growth, followed soon after by the development of breasts and pubic hair. Menstruation typically starts after the rate of growth has peaked. In boys, puberty begins with testicular enlargement, followed soon after by a growth spurt and the development of pubic hair. In clinical practice, Tanner staging is used as a method of documenting progression of physical changes that occur during puberty (Fig. 31.5). The average age at onset of puberty in the UK is about 11 years in girls and 12 years in boys, but normal puberty has a very wide range of onset. Factors that are important in predicting age of onset of normal puberty include family history (age of onset is strongly predicted by the parents' pattern of onset) and body mass, with heavier children entering puberty at a younger age. The current trends towards improved nutritional status and increased obesity in particular are driving earlier onset of puberty. Delayed puberty is defined to have occurred when the age at onset is more than 2.5 standard deviations above the national average, which in the UK is about 13 years in girls and 14 years in boys. If puberty is delayed beyond this point, investigations may be needed to determine the underlying cause. Many children who have had long-term health conditions during childhood experience a delayed onset of puberty because chronic ill health slows longitudinal growth and causes functional hypogonadotrophic hypogonadism. Glucocorticoid therapy also contributes to growth retardation in children with chronic inflammatory diseases. An X-ray of the left wrist can be used to assess bone age accurately (Fig. 31.6), and a bone age that is more than 2 years behind the chronological age should prompt consideration of further investigations.

Cognitive and behavioural changes

As young people move from their early teenage years to later adolescence there is a move away from the family towards personal independence. This is often characterised by change from a self-centred focus,



12 years
14 years
16 years
18 years
20 years
22 years
24 years
26 years
Make aware of transition planning
Initiate planning
Prepare for adult model Discuss transfer
Transfer to adult service with transfer package
Integrate into adult care

A
Higher cerebral centres 'trigger' puberty
GnRH
Pituitary LH and FSH secretion increased
Prolactin
ACTH
LH and FSH
Acne appears
Axillary hair appears
Breasts develop
Uterus enlarges
Menstruation begins
Vaginal epithelium cornifies
Pubic hair appears
Body contours rounded
Epiphyseal union hastened
Adrenal androgens increased
Adrenal cortices
Reticular zone enlarges
Oestrogen produced
Ovaries
Progesterone increased
B
Higher cerebral centres 'trigger' puberty
GnRH
Pituitary LH and LSH secretion increased
Prolactin
ACTH
LH and FSH
Adrenal cortices
Adrenal androgens increased
Reticular zone enlarges
Testes
Testosterone increased
Acne appears
Facial hair appears
Musculature develops
Larynx enlarges (voice deepens)
Axillary hair appears
Some breast enlargement may occur
Pubic hair appears
Penis, prostate and seminal vesicles enlarge
Epiphyseal union hastened

Fig. 31.4 **Hormonal events of puberty.** **A** In the ovary, FSH acts on granulosa cells to stimulate oestrogen production, whereas LH acts on theca cells to stimulate progesterone production. Androgens are also produced in small amounts by theca cells in response to LH (not shown). **B** In the male, LH acts on interstitial Leydig cells to stimulate testosterone production. FSH with testosterone acts on Sertoli cells to stimulate spermatogenesis. (ACTH = adrenocorticotrophic hormone; FSH = follicle-stimulating hormone; GnRH = gonadotrophin-releasing hormone; LH = luteinising hormone) *From Smith RP. Netter's obstetrics and gynecology, 2nd ed. Philadelphia: Saunders, Elsevier, Inc.; 2008.*

Tanner stage	I	II	III	IV	V
Female					
					Breast	Pre-adolescent	Elevation of breast and papilla as a small mound	Further enlargement of breast and areola with no separation of contours	Projection of areola and papilla to form mound above breast	Mature stage. Projection of papilla with recession of areola to contour of breast
					Pubic hair	None	Sparse, long and straight	Darker, coarse and curled hair	Darker, coarse and curled hair but covering smaller area than in adult. No spread to medial surface of thighs	Dark, coarse and curled hair extending to inner thighs
Male					
					Genitalia	Pre-adolescent	Growth of testes and scrotum. Skin on scrotum reddens and becomes wrinkled	Growth of penis and further growth of testes and scrotum. Skin of scrotum becomes darker and more wrinkled	Further growth in length and width of penis, testes and scrotum	Penis, testes and scrotum of adult size
Pubic hair	None	Sparse, long and straight	Darker, coarse and curled hair	Darker, coarse and curled hair but covering smaller area than in adult	Dark, coarse and curled hair extending toward umbilicus

Fig. 31.5 Tanner staging of puberty.

associated with a sense of awkwardness and worries about being normal, towards increased self-confidence and an awareness of weaknesses in parents and others in authority. In late adolescence, young people reach a stage of self-reliance, increased emotional stability and improved ability to think ideas through. Finally, young adults begin to develop firm belief systems, autonomy and independence. With time, there is reduced conflict with parents and other figures in authority and full maturity develops.

In terms of cognition, there is a transition from being mostly interested in the present, in short-term outcomes and instant gratification, through to increased concern for the future and a greater focus on one's longer-term role in life. Sexuality, gender and relationships clarify during adolescence, and individuals move from early awkwardness and uncertainty to a firmer sense of their sexual and gender identity.

Investigations

Several changes take place during adolescence in terms of skeletal growth, organ development and body composition, which can influence the interpretation of results. Examples include fusion of the epiphyses as puberty progresses, increases in bone mineral content and density as the skeleton grows, and changes in the reference range of certain biochemical tests. Most of these changes occur gradually during puberty and there are rarely abrupt alterations in adult biochemical concentrations. It is important to use age-adjusted biochemical reference ranges until puberty has been completed. Several biochemical changes take place in the composition of body fluids between infancy and puberty.

Some of the key changes in biochemical markers are outlined in Box 31.4. More detail on reference ranges for specific analytes is provided in Box 33.9. The elevation in alkaline phosphatase (ALP) levels during adolescence relates to the bone isoenzyme produced by osteoblasts in the growing skeleton during the growth spurt. Further investigations for raised levels of ALP are not required in adolescence, as long as other liver function tests, including γ-glutamyl transferase (GGT), are normal.

In general, under normal physiological conditions, the reference ranges of most biochemical tests remain fairly constant between puberty and menopause in women and between puberty and middle age in men.

Clinical assessment

The initial patient consultation at transition is of vital importance for establishing a potentially life-long professional relationship with the patient, as well

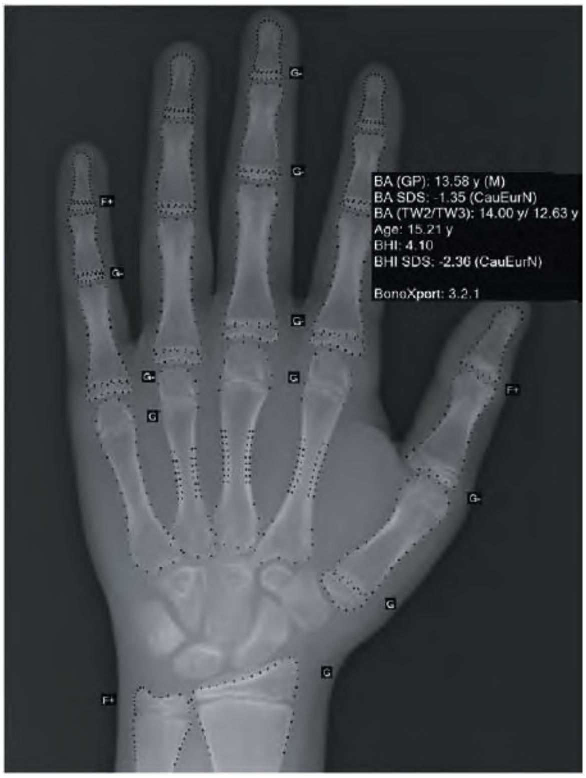

Fig. 31.6 Assessment of bone age in X-ray of left hand and wrist. The pattern of epiphyseal plate closure is used to assess maturity of the skeleton. In this example, the individual had a chronological age of 15.21 years and a bone age of 13.58 years.

i 31.4 Biochemical changes during transition

Analyte	Comment
Alanine aminotransferase (ALT)	Increased during adolescence Activity may continue to rise, at least in men, until middle age
Alkaline phosphatase (ALP)	Activity higher in infancy, decreases during childhood, and rises again with skeletal growth during puberty Peak in females at median 11 years and in males at 13 years Levels decrease rapidly after puberty, particularly in girls; adult levels achieved after epiphyses fused
Insulin-like growth factor 1	Levels 30% higher during adolescence
Serum creatinine	Increases steadily from infancy to puberty parallel to development of skeletal muscle; until puberty, there is little difference in concentration between males and females
Uric acid	Decreases from high levels at birth until 7–10 years of age, then increases, especially in boys, until 16 years

i 31.5 Features in transition assessment

Features of history and/or examination	Reason
History*	
Main/presenting condition and detailed review of clinical course	Understand detail and severity of illness; understand which treatments have been undertaken and which have been successful
Family history: Draw family tree of all first-degree and any relevant/affected second-degree family members	Many long-term conditions arising during childhood have significant genetic and familial factors to be taken into account
Current drug therapy, significant previous therapies	Many drugs have significant long-term implications, levels may need monitoring, may have teratogenic effects to consider
Any surgical or other relevant medical history	Understand which treatments have been undertaken and which have been successful
Pubertal status/age of menarche	Helps assess disease severity plus patterns of growth Informs about patient's reproductive health and family-planning wishes
Social history: In education or in work? Receiving appropriate benefits/support? Financial or other practical concerns? Living with parents/left home?	Assesses wider effects of patient's health on their independent living, as well as their financial and practical circumstances Can be a proxy measure of disease severity and identifies their support mechanisms, which also helps in the assessment of their current needs
Systems enquiry	Any other related/unrelated symptoms or problems
Physical examination	
Height, weight, calculation of body mass index Blood pressure Urinalysis if relevant Assessment of pubertal status General physical examination	Although young people are often accompanied by a parent, examine them separately and use this opportunity to consider asking about private matters, such as partners, sexual activity and drug or alcohol use

*Throughout the first consultation, confidence and competence in decision-making/capacity to consent should be assessed. If there are concerns about capacity, clarify key decision-makers.

as identifying key features in the history, examination and assessment of their overall needs. Parents commonly attend a first adult appointment with their son or daughter, and it is usually necessary to allow longer for this initial assessment. Often, the first transition appointment is undertaken jointly with the adult clinician and the paediatrician in a specialist transition clinic, and this will enable a thorough face-to-face handover of all the key facts.

A detailed transition referral letter should clearly describe the diagnosis, current and previous treatments, and key interventions that have been undertaken while the patient was under the care of paediatric services. It is important to check the main details with the young person and to make sure there are no other factors that they feel are of relevance. There are a few features in the history that merit special attention, particularly at the first consultation, as outlined in Box 31.5. Many young people with a LTC attend their first adult outpatient department consultation with their parents, and it is important either to create a time to ask personal and lifestyle-related questions separately from the main history – that is, privately – or to make sure that these can be confidentially explored in future.

Specific challenges during adolescence

Adherence

Adherence is defined as 'the extent to which a person's behaviour, in terms of taking medications, following diets or executing lifestyle changes, coincides with medical or health advice'. The term 'adherence' is used in preference to 'compliance' because it focuses on whether a person actively adheres to the regimen rather than passively follows the doctor's orders. It also implies partnership and cooperation between the patient and the care-giver. More recently, clinicians have moved to seeking patients' concordance with management plans. 'Concordance' refers to a consultation process that has an underlying ethos of shared decision-making. It has become clear that current levels of adherence do not deliver the full benefits of medication. Historical paternalistic medical practice does not maximise the chances of patients adopting the changes and treatments they need to improve their outcomes. Reaching a concordant position with patients involves a range of approaches (such as patient-centredness or shared decision-making) and a number of specific actions (such as exploring anxieties about medication side-effects, individualising regimens to suit the patient's lifestyle, offering a range of treatment options) and has not been evaluated comprehensively.

Adherence to clinic attendance, investigation and treatment often falls significantly in adolescence and during transition to adult services. Measurement of adherence is challenging, and reported rates vary according to the method of assessment. Adolescents may also have varying adherence levels within their treatment regimen. An important example is in patients who have undergone organ transplantation, in whom low adherence to immunosuppressive medication is a significant cause of graft rejection and may cause death. Adherence merits careful consideration when caring for adolescents and young adults, and focusing on strategies to improve adherence at this initial stage of patient management can deliver life-long improvements in health outcomes. Young teenagers mainly believe in things that they have directly experienced and do not fully appreciate the unseen consequences of not taking their medications. In time, adolescents learn to develop hypothetical thinking and to analyse more complex information and decision-making. The ability to engage in formal thinking is inconsistent at first, and at times of stress (such as during an illness) adolescents may regress to more simple ways of problem-solving. Despite their maturing skills, they may remain self-centred and feel invincible. Factors that positively and negatively affect adherence are outlined in Box 31.6. Interventions to improve adherence are summarised in Box 31.7.

Recent literature suggests that two-way communication between patients and professionals about medicines leads to improved satisfaction with care, knowledge of the condition and treatment, adherence, health outcomes and fewer medication-related problems. Younger adults and those coming to adult services following transition from paediatric services have very different expectations in terms of the nature of the patient–doctor relationship and are more likely to require a more collaborative approach to development of management plans to maximise their concordance with treatment in the long term.

High-risk behaviour

The high-risk behaviour that can be undertaken by adolescents is well documented and is seen across many cultures. It is important to assess this by history-taking at the time of transition (Box 31.8). Adolescents who have had LTCs during childhood are at greater risk of undertaking harmful behaviour, and there is evidence that a poor long-term health outlook is associated with risk-taking behaviour earlier in life.

31.6 Factors affecting adherence

Negative factors

- Older adolescent
- Mental health issues with care-giver
- Family conflicts
- Complex therapy
- Medication with side-effects
- Denial of illness

Positive factors

- Positive family functioning
- Close friends
- Internal locus of control
- Treatment with immediate benefits
- Patient's belief in seriousness of illness and efficacy of treatment
- Physician empathy

31.7 SIMPLE strategies to improve adherence

Simplify regimen

- Use once daily/twice daily regimens if possible
- Match regimen to bedtime and meals
- Use pill box or alarms on phone
- Organise services around patient (combined clinics, flexible timing and appointments)

Impart knowledge

- Share decision-making
- Provide clear instructions:
  - Limit to three or four major points
  - Use simple, everyday language
  - Use written information or pamphlets and verbal education at all encounters
- Supply addresses of quality websites
- Provide advice on how to cope with medication costs

Modify patient beliefs

- Empower patients to self-manage their condition:
  - Ask about their needs
  - Ask what might help them become and remain adherent
  - Ensure they understand the risks of not taking their medication
  - Address fears and concerns about taking the medication

Provide communication

- Improve interviewing skills
- Practise active listening
- Provide emotional support – treat the whole patient and not just the disease
- Provide clear, direct and thorough information
- Elicit the patient's input in treatment decisions
- Allow adequate time for patients to ask questions
- Build trust

Leave the bias

- Learn more about low health literacy and how it affects patient outcomes
- Consider care of ethnically and socially diverse patient populations
- Acknowledge biases in medical decision-making (intentional or unintentional)
- Address dissonance of patient–provider race/ethnicity and language
- Take extra time to overcome cultural barriers
- Ask specifically about attitudes, beliefs and cultural norms around medication
- Use culturally and linguistically appropriate targeted patient interventions
- Increase engagement, activation and empowerment
- Tailor education to the patient's level of understanding

Evaluate adherence

- Direct:
  Number of repeat prescriptions
  Biomarkers of response
  Measurement of drug levels
- Indirect:
  Self-reporting: 'When did you last forget your medicine?'; 'How often have you forgotten your medicines this week?'

31.8 History-taking in adolescent patients

Home life

- Relationships
- Social support
- Household chores

Education

- School
- Exams
- Work experience
- Career
- University
- Financial issues

Activities

- Peers, people that patients can rely on
- Exercise and sport

Driving

- Aged 16 if disabled

Drugs

- Cigarettes and alcohol: how much, how often
- Non-prescription drugs

Diet

- Nutritional content (calcium, vitamin D)
- Weight
- Caffeine (diet drinks)
- Binges/vomiting

Sex

- Concerns
- Periods
- Contraception (in relation to medication)

Sleep

- Amount
- Difficulty getting to sleep
- Frequent waking
- Early waking?

Suicide

- Depression
- Mood
- Disabled adolescent men high risk

31.9 Terms in use to describe gender identity

- **Gender fluid**: a gender identity or expression that involves moving between genders or having a gender that changes over time.
- **Gender questioning**: refers to a person who is in the process of exploration or discovery regarding their gender identity or expression.
- **Transgender**: refers to a person whose gender identity does not match their assigned sex at birth.
- **Gender conforming**: an umbrella term that describes anyone whose gender expression or identity aligns with traditional societal norms.
- **Gender non-conforming**: an umbrella term that describes anyone whose gender expression or identity does not align with traditional societal expectations.
- **Assumed gender**: a gender attributed to an individual based on societal norms and expectations, often relying on superficial physical characteristics.
- **Agender**: refers to a person who does not identify with any gender identity, preferring neutral pronouns such as they.
- **Bigender**: refers to a person who identifies with both male and female genders, either simultaneously or at variable times.
- **Androgyny**: refers to a person whose gender expression incorporates both masculine and feminine elements. It can describe either a gender expression or a gender identity.
- **Cisgender**: refers to a person whose gender identity matches the gender assigned to them at birth, usually based on their biological sex.
- **Omnigender**: a gender identity where a person identifies as a mixture of several genders or as all genders simultaneously.
- **Non-binary**: a gender that does not fit into the traditional male–female binary.

Globally, the leading causes of death among adolescents are injuries (including road traffic accidents and drowning), suicide and interpersonal violence; some of these deaths are linked to risk-taking behaviours. Quite apart from mortality, there are other significant adverse events linked to risk-taking behaviour in adolescents: excess alcohol ingestion and drug use are also associated with non-fatal road traffic accidents, unwanted and unprotected sexual activity, and violence as both perpetrator and victim.

There are a number of theories about the neurodevelopmental changes associated with these behaviour shifts. At around 11 years of age, the prefrontal cortex (PFC) and parietal lobes begin a period of pruning of neuronal axons. It is theorised that these changes represent the start of the process of increasing frontal lobe control. A separate process that occurs at the same time predisposes the adolescent to risk-taking behaviour and impulsivity: frontostriatal reward circuits mature relatively early and encourage the adolescent towards adult activities such as alcohol and drug use, and sexual intercourse, which carry potential health risks. At this stage, the PFC has not yet matured to the point where the individual can assess risk adequately. The PFC and its connections are structurally unable to provide sufficient control. It is thought that this maturational gap in PFC control of the pleasure-seeking brain systems is responsible for the risk-taking lifestyle that characterises the period of adolescence.

A number of studies have investigated personality and other factors that contribute to different risk-taking behaviours during adolescence: essentially, younger adolescents and females tend to rate activities as being more risky and are therefore less likely to undertake them. Older males and those of lower educational status are higher-risk takers. Specific protective factors include high self-esteem and a strong orientation to an internal locus of control; young people who feel they have less control and influence over themselves and their behaviour are more likely to undertake high-risk activities. Many young people with serious long-term health conditions are disempowered in a number of ways and there is evidence that they are predisposed to be high-risk takers during adolescence. Examples of risk-taking behaviour include not only alcohol and drug intake, but also non-adherence to medicines and other aspects of health care, such as diet in diabetes.

It is not easy to affect behaviour during this period of non-adherence. Isolated educational intervention is not sufficient to improve outcome; for example, there is a wealth of evidence showing that adolescents know about the behaviours needed to prevent sexually transmitted disease, but many do not adhere to this advice. Long-term health-care providers have an invaluable role in supporting adolescents during this period of their development as adults, as many important health-related and lifestyle habits are established during this period: more than 90% of smokers start smoking in adolescence, and life-long habits around eating and exercise are laid down during the teenage years. Focusing on the needs of the emerging adult for autonomy and using the highest levels of communication and patient engagement significantly improve outcomes for patients with LTCs.

Gender exploration and affirmation

Adolescence is a journey of becoming an independent and unique adult human, which involves separation from parents and imposed beliefs systems, questioning social norms and exploring one's place in society. It is, therefore, no wonder that gender questioning is common among adolescents. It is more common in Western society, but it is not unique to developed countries.

There is no consensus on best language to use around this subject. Labels are inherently challenging, confusing and sometimes alienating. Gender incongruence is the term used in the ICD-11 (2022) to describe 'a marked and persistent incongruence between an individual's experienced gender and the assigned sex', whereas gender dysphoria is defined in the DSM-5 (2022) as 'Gender incongruence that is *associated with clinically significant distress or impairment of function*'. Many other phrases are used within this area by young people (Box 31.9). Preferred pronouns should be sought and used effectively in discussions, remembering that both pronouns and gender expression may change over time.

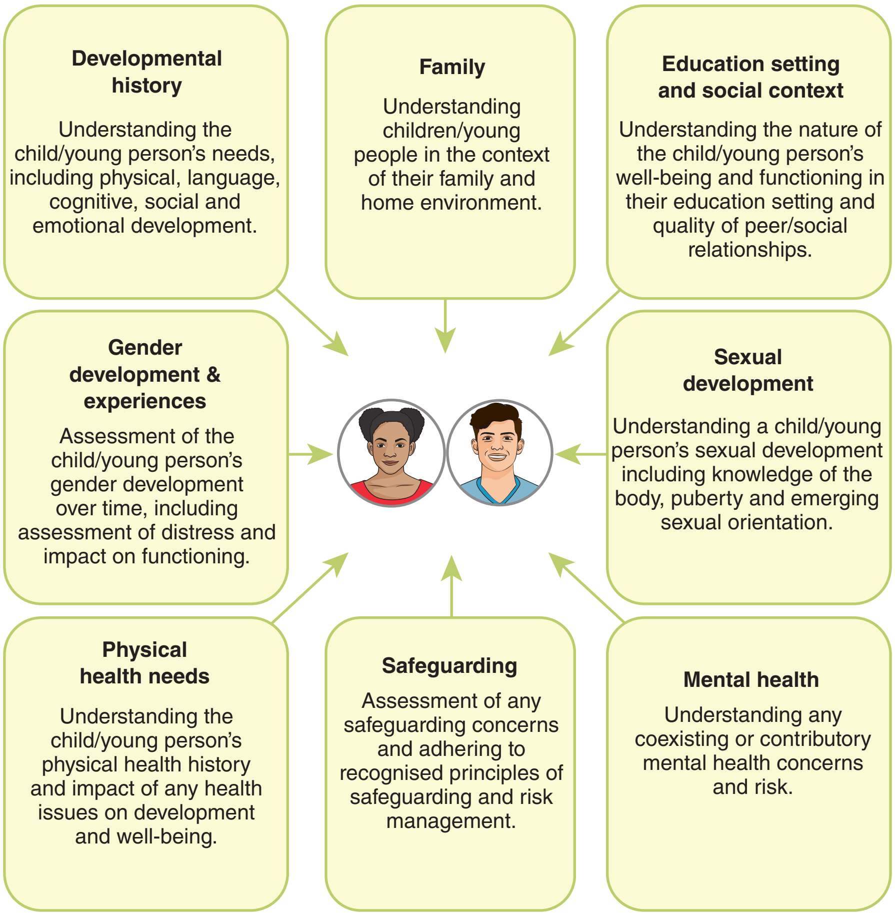
There has been a rise in referrals to specialist services for children and young people experiencing gender-related distress. The rise in prevalence over the last decade is significantly greater in young females, with an exponential rise between 2009 and 2016 in the UK, a pattern replicated internationally. The emerging patterns need to be more fully understood, but it is clear that there are multiple reasons for gender incongruence, including biological, psychological and social factors. Simplistic explanations that do not embrace the complex interplay of factors risk undermining or undervaluing the young person's experience of gender-related distress. There is value, however, in studying the shifts in societal and cultural norms that this generation have been exposed to, having seen a dramatic increase in the numbers seeking support around their gender identity. It is possible that their lived experience of unparalleled online access has adapted and enhanced the socially conscious brain in ways we are yet to discover. Alongside an increase in young people expressing gender incongruence, there has been an increase in emotional distress, poorer mental health and greater recognition and diagnosis of neurodiversity.

The optimal clinical approach to gender incongruence and/or dysphoria is not clearly defined. There is extensive variation in practice globally and a paucity of evidence-based research on which to base practice. A significant challenge is the lack of data on long-term outcome. In the face of uncertainty, there are understandably differing and sometimes diverging approaches. Some countries are preferring a gender-affirming service, while others a gender-explorative service. However, it is generally accepted that a clinical assessment should be holistic in nature, involve a multiprofessional team and be a collaborative process with the young person. The child and their family's needs must be explored in an open way, and the assessing team should then seek to identify options for support and treatment that meet individual needs. A stepped pathway is most often the recommended approach, while acknowledging that there is no validated tool for assessment to help guide a universally adopted pathway.

A holistic needs assessment addressing multiple components should be undertaken (Fig. 31.7). This conversation aids a formulation which informs the creation of a care plan. Aspects that a care plan might include are shown in Box 31.10. Most services focus on psychosocial support first and foremost, while others consider that this is not always necessary. Overall, this is a complex and emerging area of medicine that should not be undertaken outside specialist services (Box 31.11).

Unplanned pregnancy

In many parts of the world, females commonly undergo their first pregnancy during or just after adolescence. The median age for first pregnancy varies from 19 years in India and parts of Asia, through to 25 years in the United States and around 30 years in Australia and Western Europe. Teenage pregnancy rates are high across the world (Box 31.12). Information from the UK suggests that 1 in 6 pregnancies is unplanned, and 1.5% of women between the ages of 18 and 45 face an unplanned pregnancy each year. It is therefore vital to anticipate and discuss the issues surrounding reproductive health with all young people before and during transition, as well as during early adulthood. Young people with serious LTCs have a number of additional factors to be taken into consideration when discussing reproduction, and these discussions need to take place long before a family is planned. General physicians do not need to be able to undertake complex genetic counselling and investigation, but should be able to provide advice about the recurrence risk of common inherited conditions, as well as that of the more common multifactorial LTCs, many of which have an inherited or genetic component.



Developmental history
Understanding the child/young person's needs, including physical, language, cognitive, social and emotional development.

Family
Understanding children/young people in the context of their family and home environment.

Education setting and social context
Understanding the nature of the child/young person's well-being and functioning in their education setting and quality of peer/social relationships.

Gender development & experiences
Assessment of the child/young person's gender development over time, including assessment of distress and impact on functioning.

Sexual development
Understanding a child/young person's sexual development including knowledge of the body, puberty and emerging sexual orientation.

Physical health needs
Understanding the child/young person's physical health history and impact of any health issues on development and well-being.

Safeguarding
Assessment of any safeguarding concerns and adhering to recognised principles of safeguarding and risk management.

Mental health
Understanding any coexisting or contributory mental health concerns and risk.

Fig. 31.7 Components of a needs-based assessment for young adults with gender dysphoria. *Source: The Cass review: independent review of gender identity services for children and young people. cass.independent-review.uk/wp-content/uploads/2024/04/CassReview_Final.pdf*

i 31.10 Example of interventions that could be used for young adults presenting with gender dysphoria

- **Individualised care plan**
- **Psychosocial support** (e.g. liaison with school, social prescribing, connecting with peer networks, social care engagement, validation)
- **Therapeutic intervention** (e.g. targeted at identified need such as depression, anxiety, OCD)
- **Educational support** (e.g. identify unmet need, communicate with school, help access ASC/ADHD assessments, help access arrangements for exams if school attendance affected)
- **Parent/carer support** (e.g. signpost to carer forums, education, discussion and support space)
- **Support from local professional networks** (e.g. refer, signpost, access)
- **Referral for endocrine or specialist assessment** (e.g. specialist gender identity clinic, which may involve discussion of medical and surgical treatment options)

(ADHD = attention deficit/hyperactivity disorder; ASC = autism spectrum condition; OCD = obsessive–compulsive disorder)

i 31.11 Challenges and cautions within gender dysphoria clinical practice

- The effectiveness of puberty blockers is unproven at this moment in time, and the benefits/harms unknown.
- Systematic reviews have highlighted a lack of understanding around longitudinal outcomes for adolescents prescribed hormonal interventions.
- While we do not know the long-term impacts of embarking on these medical treatments in childhood/adolescence, caution must be exercised.
- It is extremely challenging to seek informed consent for treatment when there are so many unknowns.
- Research on outcomes and longitudinal data on those that receive psychosocial interventions as opposed to endocrine interventions is also lacking.
- There is a strong argument for improving the evidence base for both medical and non-medical interventions in this area of adolescent health.

i 31.12 Adolescent pregnancy rates/1000 women aged 15–19 years (2018)

Region	Pregnancy rate

Clinical presentations

In almost every clinical setting, there is the potential for a young adult with a serious LTC that has arisen during childhood to present to adult physicians. Medical services can improve the care and outcome for this vulnerable group by planning a systematic approach to transition, as described above, and by focusing the clinical consultation on issues of relevance and importance to each particular patient. The key issues to consider for a number of the most common LTCs of childhood are discussed below.

Neurological disease

Epilepsy

Epilepsy is a chronic disorder, the hallmark of which is recurrent, unprovoked seizures (p. 1197). Epilepsy that has presented during childhood, as opposed to adulthood, is less often associated with underlying central nervous system malignancy and is well controlled with first-line anticonvulsants in around 80% of cases. Young people who still have epilepsy or are on anticonvulsant therapy as they progress into adulthood are more likely to have underlying structural brain disease, such as cerebral palsy, or have more complex or syndromic epilepsy. In many of them, epilepsy may be associated with learning difficulties or other neurological conditions.

Epilepsy presents several problems during transition. Adherence to medication can be an issue and patients with low adherence to epilepsy medicines have higher mortality, higher hospital admission rates and higher emergency department attendances. Conversely, high adherence rates at initiation of epilepsy therapy are associated with improved long-term seizure freedom and higher seizure freedom at 4 years. Epilepsy can also affect employment options for young people, as about 30% of patients still have breakthrough seizures while on treatment. Certain types of employment, such as working within the emergency services or armed forces, or becoming a pilot or driver of a heavy goods vehicle, may therefore not be possible. Driving restrictions may also limit options for some other occupations. Young women with epilepsy should be advised that oral contraceptives are less effective with enzyme-inducing antiepileptic drugs; they should also be made aware of the risk of teratogenicity with many antiepileptic drugs, most notably sodium valproate, which should be avoided in pregnancy if at all possible. Pre-conceptual counselling is desirable for all young girls with epilepsy and pre-conceptual folic acid supplementation is advisable to reduce the risk of neural tube defects.

Alcohol use in moderation does not affect seizure control in the majority of patients, but withdrawal from alcohol in dependent patients is epileptogenic and heavy alcohol use should be discouraged. Information about marijuana and epilepsy risk is lacking, but regular marijuana use and excess drinking are associated with poor adherence to medication regimens and increased seizure risk.

Cerebral palsy

Cerebral palsy comprises a range of non-progressive neurological impairments, present from the time of birth or arising in early childhood. Although the neuropathology is non-progressive, the manifestation of problems can evolve, with progressive motor dysfunction related to increased spasticity and possibly progressive seizure activity.

Patients with severe cerebral palsy present specific problems during transition and early adulthood. They may be paraplegic or quadriplegic and most non-ambulatory individuals have significant intellectual disability. This group of patients will be unable to live independently during adulthood and need ongoing long-term care. Delivering medical care to these individuals poses several problems, including practical issues such as consideration of capacity and consent to treatment. Other comorbidities include gastro-oesophageal reflux (often related to abnormal lower oesophageal function), seizures and feeding difficulties often requiring gastrostomy. These individuals usually require a complex care package involving many members of the multidisciplinary team. There are also risks of abuse and neglect in the care of adults with severe disability, and this needs to be borne in mind when considering atypical problems or unusual presentations in this vulnerable patient group. Depending on the severity of the patient's condition, end-of-life care may need to be discussed and planned with the family and other care-givers.

Muscular dystrophy

The muscular dystrophies are a group of diseases that cause progressive weakness and loss of muscle mass (p. 1240). The disorders differ in terms of which muscle groups are affected, the degree of weakness and the rate of disease and symptom progression. All the inherited muscular dystrophies that present during childhood need active management during transition. One of the most severe conditions is Duchenne muscular dystrophy (DMD), which presents usually between the ages of 2 and 3 and leads to increasing muscle weakness and eventual premature death in the second or third decade of life due to cardiomyopathy and respiratory failure. Those with less severe muscular dystrophies, such as Becker dystrophy, survive until their thirties.

Female carriers of the pathogenic variations in the *DMD* gene can suffer muscle fatigue and are at risk of cardiomyopathy, as well as there being obvious risks for their male offspring. Physicians should ensure that the whole family is aware of the wider genetic issues. Although fertility is reduced, young men with these conditions may themselves father children. Male offspring will be unaffected but all female infants of affected males will be carriers. As the muscular dystrophies progress, a complex package of care involving a multidisciplinary team is necessary; it should include respiratory input to assess the need for ventilatory support, which is a common endpoint for many patients.

Glucocorticoids (prednisolone at 0.75 mg/kg/day) are the cornerstone of treatment in DMD and have been shown to improve muscle strength and are frequently used, but carry an increased risk of osteoporosis and vertebral fractures.

The *DMD* gene encodes dystrophin, a major structural component of muscle; pathological variants affect the structure and function of the protein. It is now possible to perform a gene therapy technique called 'exon skipping', whereby the exon containing the pathological variation is masked (i.e. covered up) using antisense oligonucleotides, resulting in a truncated but still functioning protein called micro-dystrophin. Not all patients respond to, or are candidates for, antisense oligonucleotides. It is estimated that about 8% of patients with DMD have a pathogenic variation amenable to exon 53 skipping and about 13% of patients have a pathogenic variation amenable to exon 51 skipping. Some antisense oligonucleotides have recently been approved by the FDA (such as Elevidys, an adeno-associated virus vector-based therapy). Although evidence is limited, these treatments do appear to ameliorate muscle degeneration in appropriate patients, extending mobility and delaying the progression of symptoms; they are not cures for DMD.

Patients with DMD and the families caring for them usually require significant medical, social and financial support. It is important to consider end-of-life care plans with patients and family members. Involvement from palliative care teams, as well as psychological, spiritual and wider non-medical support, is essential.

Respiratory disease

Cystic fibrosis

Cystic fibrosis (CF) is a single-gene autosomal recessive disorder that affects about 1 in 2000 to 1 in 3000 individuals of European descent (p. 548). Clinical manifestations, such as bronchiectasis (Fig. 31.8) and pancreatic insufficiency (both exocrine and endocrine), are caused by defects in an ion transporter termed the cystic fibrosis transmembrane conductor regulator (CFTR) protein. With improved supportive care, the median survival in the UK is now more than 50 years. It is well recognised that young people with life-limiting conditions face particular challenges during transition: individuals often exhibit high-risk behaviour during adolescence, and this was particularly true in the past when long-term survival rates were poor. The rates of adherence to medication and to time-consuming physiotherapy and nebuliser regimens are low, and this adversely affects outcome and survival. Exercise tolerance and employment are likely to be restricted as time progresses, and patients need particular support managing the slow decline in function and well-being that occurs throughout their adult lives.

In terms of fertility and child-bearing potential, the picture is complex and merits detailed discussion with patients. It is not often discussed openly by the paediatric teams during childhood, other than with the parents when the patient is young. The vas deferens is absent in 98% of males with CF, and seminal vesicular dysfunction means that ejaculates are low in volume. While boys are infertile, newer reproductive therapies, such as the availability of intracytoplasmic sperm injection, mean that fatherhood is possible. The opportunity for assisted reproduction should be discussed early so that people can make informed choices at an appropriate stage of their lives. Females with CF who have good nutritional status and reasonable health status have normal fertility, and genetic counselling should be offered early. Contraception needs to be

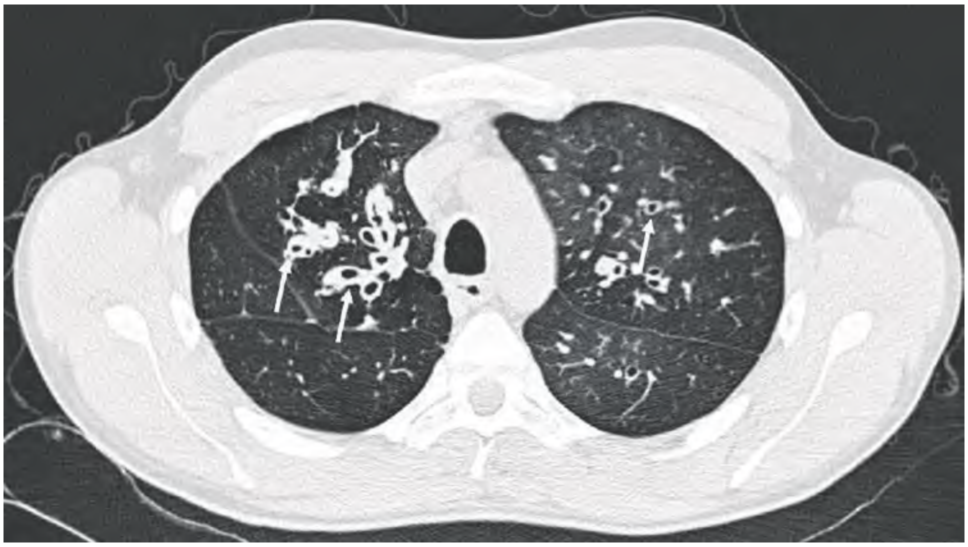

Fig. 31.8 CT scan demonstrating central bronchiectasis with bronchial dilatation and wall thickening (arrows) consistent with bronchiectasis in a patient with cystic fibrosis.

discussed with women who are not planning a pregnancy, since pulmonary hypertension is an absolute contraindication for the oral contraceptive pill (OCP). Women also need to be advised about the effects of antibiotics on OCP effectiveness.

Oral small-molecule therapies, including lumacaftor and ivacaftor (CFTR modulators), can partially rectify functional defects in the CTFR protein and have improved outcome. These drugs are having a positive effect on symptom control and are potentially disease-modifying. The triple drug combination of elexacaftor–tezacaftor–ivacaftor is an important new therapy for individuals who have at least one *F508del* mutation, which includes approximately 85% of people with CF in the United States. Other therapeutic approaches, including gene therapy and mRNA-editing therapies, are also being explored as treatments for CF. Common issues encountered during transition of CF patients are summarised in Box 17.35.

Cardiovascular disease

Congenital heart disease

Congenital heart disease (CHD) is the most common congenital anomaly, affecting about 1% of live births. Among birth defects, CHD is the leading cause of mortality. Maternal illnesses such as rubella and injection of teratogenic agents during pregnancy, along with paternal age, all play roles in pathogenesis. Although some chromosomal anomalies, such as trisomy 13, 18 and 21 and monosomy X (Turner syndrome), are strongly associated with CHD, these account for only 5% of cases. Microdeletion and single-gene mutations can also be important, such as in DiGeorge syndrome (22q11.2 microdeletion). Overall, the most common congenital valvular anomalies are aortic and pulmonary stenosis. The most common structural anomaly is ventricular septal defect.

There is a wide range of severity of CHD, but many patients with life-limiting conditions (usually complex structural anomalies such as tetralogy of Fallot or hypoplastic left heart syndrome) survive to adulthood. Genetic counselling of affected individuals is important, as there is a 1%–2% recurrence risk of any cardiac anomaly in offspring. Affected patients should be transitioned to a cardiologist with experience in CHD, since this has become a subspecialty in its own right. More details are provided on page 503 and in Box 16.103.

Hypertrophic obstructive cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM) is characterised by left ventricular wall hypertrophy, impaired diastolic filling and abnormalities of the mitral valve (p. 511). These features can cause dynamic obstruction of the left ventricular outflow tract, diastolic dysfunction, myocardial dysfunction and an increased risk of supraventricular and ventricular tachyarrhythmias. HOCM is a genetic disorder caused by mutations affecting the genes that encode cardiac sarcomere proteins and is most frequently transmitted as an autosomal dominant trait. It may present for the first time during adolescence with cardiac arrest or sudden cardiac death. Predictive genetic testing is possible but challenging because of the large number of causal mutations. In clinical practice, careful analysis of the family history can be useful in identifying those at risk of inheriting the disease. If no gene anomaly has been identified within a family, first-degree relatives may need screening by electrocardiography (ECG) and echocardiography. Identification of a genetic anomaly is most helpful in allowing identification of family members who do not need echocardiograms or clinical follow-up. Children of affected parents should be screened every 3 years until puberty, and then annually until 20 years of age. If there is no evidence of HOCM in early adulthood, it is unlikely that the condition will develop in later life.

Oncology

Around 1 child in 500 will develop cancer by the age of 14 years. Leukaemia is the most common, accounting for about 33% of cases; central nervous system tumours are the next most common, accounting for around 25% of all childhood cancers. Fifty years ago, 75% of children diagnosed with cancer died, but overall survival rates now range from 75% to 80%. Between 60% and 70% of young adults who have survived childhood cancer will develop at least one medical disability, most commonly as a result of their therapy rather than their primary cancer. There is a three- to sixfold increased risk of a second cancer, with an absolute risk of about 10% before 50 years of age. It is therefore important for these individuals to be kept under surveillance during transition and beyond.

Endocrine and reproductive disturbances are the most common late effects, affecting 40%–60% of survivors, and include infertility hypopituitarism, growth hormone deficiency and pubertal delay (especially in boys) from brain irradiation. Radiotherapy to the neck can cause hypothyroidism and increases the risk of thyroid cancer.

Total-body irradiation offered as conditioning for bone marrow transplantation affects both ovarian and testicular function, and many of the chemotherapeutic agents used have adverse effects on fertility. Chemotherapy-induced ovarian failure is typically associated with high-dose alkylating agents such as cyclophosphamide, and this is an independent risk factor for premature ovarian failure. Patients may be offered ovarian and testicular tissue retention in advance of cancer therapy. Fertility issues are discussed with families during childhood, but often the patients themselves have limited levels of knowledge of the details. Young women need to be aware of these risks during their early adulthood to help with family and lifestyle planning; for example, they may wish to plan to have children earlier in their adult life rather than risking ovarian decline.

Cardiomyopathy is another complication of anthracyclines such as doxorubicin and daunorubicin. Serious cardiac complications include arrhythmias, dilated cardiomyopathy from myocardial necrosis, and angina or myocardial infarction arising from vaso-occlusion or vasospasm. Cranial irradiation is associated with an increased risk of obesity and all survivors, irrespective of whether or not they have been treated with anthracyclines and/or cranial irradiation, should be considered to be at risk of premature atherosclerotic cardiovascular disease.

In addition to physical effects, children who have faced life-threatening illness in childhood may experience psychological and family difficulties during adulthood. Cognitive impairment is more common in children who have received chemotherapy or radiotherapy to the brain, and problems can include lower IQ, problems with memory and attention, poor hand–eye coordination and behaviour or personality problems, combined with the well-recognised physical complications of cancer treatment in childhood.

Increasing recognition of these issues has resulted in active monitoring programmes for survivors of childhood cancer, who are best seen in specialist 'late effects' multidisciplinary clinics, where teams include oncologists, psychologists and specialists from other relevant disciplines.

Renal disease

Chronic kidney disease (CKD) accounts for some of the most complex long-term illnesses in childhood. The most common causes during childhood and adolescence are shown in Box 31.13. The primary pathology can be varied and many conditions have no specific treatment, but the overall approach to management of progressive renal insufficiency is the same. Internationally agreed definitions of CKD

i 31.13 Causes of renal impairment in childhood and adolescence

- Obstructive uropathy
- Renal hypoplasia/dysplasia
- Reflux nephropathy
- Focal segmental glomerular sclerosis
- Polycystic kidney disease

31.14 Staging of chronic kidney disease (CKD) in children over 2 years of age*

Stage	Glomerular filtration rate (GFR) (mL/min/1.73 m^2)	Description
1	>90	Normal or high
2	60–89	Mildly decreased
3a	45–59	Mildly to moderately decreased
3b	30–44	Moderately to severely decreased
4	15–29	Severely decreased
5	<15	Kidney failure

*Kidney Disease: Improving Global Outcomes (KDIGO) 2012 classification. Chronic kidney disease is defined either as GFR <60 mL/min/1.73 m^2 for >3 months, regardless of whether other CKD markers are present, or as GFR <60 mL/min/1.73 m^2 accompanied by evidence of structural damage or other markers of kidney abnormalities, including proteinuria, albuminuria and pathological abnormalities in histology or imaging. In adults, albumin excretion is also included in CKD staging as the level of albuminuria correlates with outcome. These data are lacking in children and so albuminuria is not used to classify paediatric CKD.

31.15 Impact of transition planning on outcome in diabetes

Intervention	Outcome measures
Disease-specific education	Lower HbA_{1c}
Generic education/skills training	Fewer acute complications: Hypoglycaemia Admissions with ketoacidosis
Transition coordinator	Lower rate of loss to follow-up
Joint paediatric/adult clinic	Fewer chronic complications: Hypertension Nephropathy Retinopathy
Separate young adult clinic	Improved self-management Improved disease-specific knowledge
Out-of-hours phone support	Improved screening for complications
Enhanced follow-up	Better quality-of-life scores

staging in children differ from those in adults and are summarised in Box 31.14. In adults the rate of albumin excretion is included in CKD definitions, as outcome correlates with the level of albuminuria, but in children similar data are lacking and so the staging system is based on glomerular filtration rate alone. The majority of children with CKD stage 3 or higher will ultimately require renal replacement therapy, but the timescale for reaching this stage can vary widely. The mainstay of support is to delay progression by treatment of secondary factors that are known to be associated with progressive decline in renal function: namely, hypertension, proteinuria and anaemia.

Organ transplantation

Children requiring renal replacement therapy are the most common recipients of kidney transplants in childhood. Liver and heart transplantation, followed by lung and small bowel transplantation, are well recognised but less commonly undertaken procedures. Non-adherence to immunosuppressive regimens during adolescence is a well-known risk factor for graft failure. The reported incidence of graft failure due to non-adherence is 10%–15%, but this is likely an under-estimate. Rates of non-adherence are highest among adolescents and young adults. As well as non-adherence to immunosuppression, non-adherence to testing and clinic attendance adversely affects the care and outcome of around 1 in 8 kidney transplant patients. Poor adherence is associated with patients with worse psychological status and family dysfunction; adherence has been shown to improve with education and increased motivational factors, as might be expected. This offers the opportunity to improve graft survival. At present, 50% of cadaveric grafts and around 68% of live donor grafts are still functioning 10 years post transplant. There is no clear difference between children and adults in survival of transplanted kidneys.

Many medications used in transplant medicine and in renal disease can have long-term effects on health. Inhibition of linear growth is seen even with low doses of glucocorticoids, such as prednisolone 0.125 mg/kg/day on a long-term basis. Alternate-day regimens are generally considered preferable in childhood. The height reduction associated with long-term glucocorticoid use in childhood is dose-dependent, and even for children with asthma treated with inhaled glucocorticoids, an average height reduction of 1.2 cm is reported. This can also be associated with delayed puberty, as well as an increased risk of osteoporosis in adulthood. Post-transplant lymphoproliferative disorders (PTLDs) are a well-recognised and potentially life-threatening complication in solid organ recipients. PTLDs are the most common malignancy complicating solid organ transplantation, accounting for 20% of all cancers. They represent a range of lymphoproliferative disorders, from infectious mononucleosis and lymphoid hyperplasia to malignant lymphoma. Most cases of PTLD are associated with Epstein–Barr virus (EBV), leading to uncontrolled B-cell proliferation and tumour formation. Up to 10% of solid organ transplant recipients develop PTLD, but the risk is almost four times higher in patients under 20 years of age, as opposed to those aged 20–50. This increased risk relates mainly to the development of EBV infection after transplantation; most adults are already EBV-seropositive at the time of transplantation and therefore at lower risk of this complication. The type of organ transplant that has been undertaken predicts PTLD risk, with the cumulative incidence over 5 years ranging from 1% to 2% in haematopoietic cell transplant and liver transplants, 1%–3% in renal transplants, 2%–6% in heart transplants and 2%–9% in lung transplants, to as high as 11%–33% in intestinal or multi-organ transplants. The different rates possibly relate to the varying degrees of immunosuppression required. The incidence of PTLD is highest in the first year after transplantation, when it is associated with the highest levels of immunosuppression.

Diabetes

Adherence and concordance with medication are a particular challenge in adolescents who have developed diabetes during childhood. Historic studies of adolescents with type 1 diabetes showed that approximately 25% missed insulin injections, 81% were not following their diet, and 29% were not measuring their glucose level and were completing a daily diary with fictitious results. Hybrid closed-loop systems (where delivery of insulin from a pump device is linked to continuous glucose monitoring) significantly improves glucose control in adolescents, presumably because they are technologically driven and so less reliant on human factors (p. 784). These systems should be cost effective as they reduce complications of diabetes, but they are expensive in the short-term and cost constraints currently limit availability in many parts of the world. Research has also shown that the outcome of diabetes is improved with a formal transition programme (Box 31.15). Good control of diabetes is particularly important during this phase since microvascular disease often emerges around time of transition, although it can occur sooner in patients with early-onset diabetes. There is also increasing interest in the use of immunotherapies (such as teplizumab) to delay, or even prevent, the development of type 1 diabetes in children and young adults (see p. 758).

Gastrointestinal disease

Inflammatory bowel disease

There has been a significant increase in the incidence and prevalence of paediatric-onset inflammatory bowel disease (IBD) over the last 25

i **31.16 Treatment strategy in Crohn disease**

- Induce and maintain clinical remission
- Optimise nutrition
- Optimise bone health
- Optimise growth and pubertal progress
- Minimise adverse drug effects

years, alongside significant progress in the tools for investigation and management. This has been quantified as a doubling in incidence in the UK over the last 2 years, with similar rates of increase in South America and Asia although with lower overall patient numbers. The incidence of Crohn disease is approximately twice that of ulcerative colitis, but it is increasingly recognised that IBD represents a complex 'continuum' disorder with a similarly complex aetiology including genetic, environmental and microbial factors (p. 853). Despite this, the treatment remains largely empirical.

Current treatment aims are outlined in Box 31.16. Standard measures in Crohn disease include exclusive enteral nutrition for 6–8 weeks using a whole-protein (polymeric) formula, which induces initial remission in 80% of children. This is equivalent to glucocorticoid therapy, but offers improved nutritional status and superior mucosal healing. Glucocorticoids can also be used to induce remission, as well as to treat exacerbations, but should be followed up by immunosuppressive therapy with azathioprine or methotrexate. Adolescents and children are more likely than adults to require biologics, and around 20% need treatment with tumour necrosis factor alpha (TNF-α) inhibitors such as infliximab or adalimumab. Around 20% of children with Crohn disease require surgery within 5 years of diagnosis; limited resections and stricturoplasty are considered best practice to preserve gut length and prevent short bowel syndrome.

Children with ulcerative colitis are more likely than adults to present with pancolitis (approximately 80% versus 40%–50% in adults). Mild disease should be treated initially with oral 5-aminosalicylic acid (5-ASA) preparations such as mesalamine or sulfasalazine. If the response is inadequate, oral glucocorticoids can be used, but caution must be exercised because of the adverse effects on skeletal growth and bone mineral density. Thiopurines such as 6-mercaptopurine or azathioprine are frequently used as glucocorticoid-sparing agents, with progression to anti-TNF-α therapy for those who still do not respond. There is less evidence for efficacy of TNF-α inhibitors in adolescents with ulcerative colitis than those with Crohn disease; they seem to be effective at inducing an initial response but less useful for maintaining long-term remission, since a significant proportion of patients still require colectomy (20% at 1 year) or long-term glucocorticoids. Ciclosporin is probably more effective than infliximab in adolescents with refractory ulcerative colitis. As with other young people who have long-term conditions, adherence to medication is particularly important to reduce the risk of relapse. In terms of lifestyle advice, smoking is a particular risk since it increases both the rate and severity of relapses. Body image can be a particular challenge for young adults with IBD, and those with colostomies or fistulae, for example, can find this part of their illness particularly difficult. Delayed puberty and short stature are important comorbidities, partly related to medication side-effects and also to the nature of the inflammatory bowel disease itself.

Rheumatology and bone disease

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term used to describe a wide variety of inflammatory rheumatic diseases that present during childhood. Oligoarticular juvenile arthritis has a good prognosis and often remits during adulthood, and so transitioning patients to adult rheumatology services may not always be required. The same does not hold true for systemic JIA and polyarticular JIA, which often require long-term immunosuppressive therapy through transition and beyond into adulthood. Smoking is a risk because it increases the activity of inflammatory disease and reduces the effectiveness of biologics. Adherence to and concordance with medication remain a challenge, as in other chronic diseases. Functional limitation secondary to joint damage may limit employment opportunities. Contraceptive advice is important in patients on methotrexate.

Glucocorticoid-induced osteoporosis

Osteoporosis is a complication of long-term glucocorticoid therapy (p. 1076) that may be acquired in patients with inflammatory disease, transplantation and DMD.

There is a paucity of evidence about best practice in glucocorticoid-induced osteoporosis in children and adolescents, but in general the teenage years are a period of considerable bone mineral deposition and offer a chance to enhance bone mineral density significantly. It is important to ensure adequate calcium and vitamin D intake and to supplement if necessary. Therapy with bisphosphonates is often initiated in patients with clinical vertebral fractures, although the evidence base for prevention of fractures with treatment in childhood and adolescence is limited.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is a genetic disorder most commonly caused by pathogenic variants in the type 1 collagen genes, which typically presents with multiple low-trauma fractures during infancy and childhood (p. 1086). The incidence of fractures falls substantially in adolescence, probably because of the increase in bone mass which occurs as the result of skeletal growth. However, the incidence of fractures in OI during transition and in young adults is about 10–100 times higher throughout life as compared with the general population. Intravenous bisphosphonates such as pamidronate and zoledronic acid are widely used in the treatment of children with osteogenesis imperfecta (those with long-bone deformities, vertebral compression fractures, and three or more fractures per year, in whom the benefit/risk ratio is thought to be positive), although the evidence base for prevention of fractures is poor and mainly based on observational studies (Fig. 31.9).

There is much debate about whether continuing bisphosphonate therapy into adulthood is beneficial due to concerns about suppression of bone turnover in the long term. Affected individuals and their parents can find this change in treatment strategy confusing, and it is important to explain the underlying rationale in order to manage expectations.

Hereditary hypophosphataemic rickets

Hereditary hypophosphataemic rickets is a group of disorders caused by pathogenic variations in genes that regulate phosphate excretion (p. 1083). Adherence to phosphate supplements and, to a lesser extent, vitamin D metabolites represents an important issue in optimising management during childhood, and this becomes even more challenging in transitioning patients. The treatment of X-linked hypophosphataemic rickets (XLH) in children has, however, been revolutionised by burosumab, a neutralising antibody to FGF23 given by subcutaneous injection once monthly, which corrects the metabolic disorder and has been shown in clinical trials to be significantly more effective in the treatment of XLH than standard care. While skeletal deformity does not progress following closure of the epiphyses, different problems arise in adolescent patients when there is suboptimal control of hypophosphataemia, including painful pseudofractures and arthralgia associated with enthesopathy. The renal phosphate leak tends to improve to an extent during adolescence and early adulthood and the requirement for phosphate is reduced, but many patients still require treatment in adulthood.

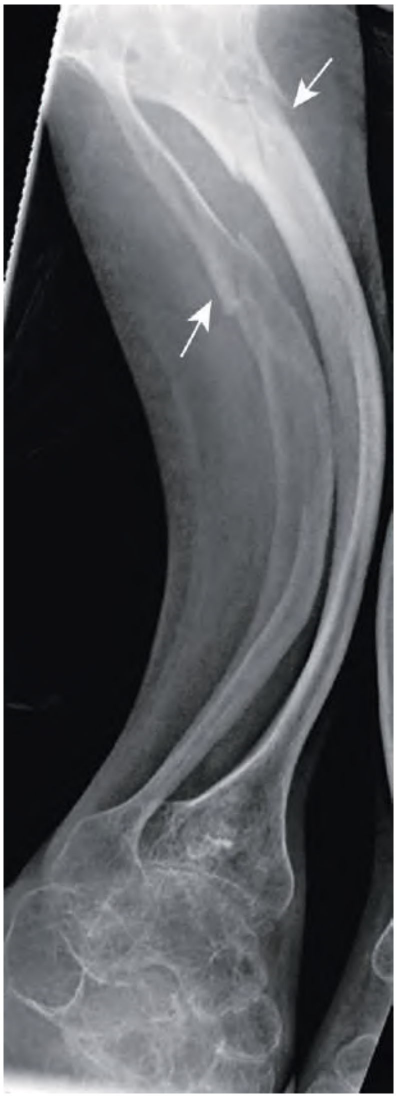

Fig. 31.9 X-rays of right tibia and fibula in a patient with osteogenesis imperfecta demonstrating bowing and fractures of the proximal shafts of both bones (arrows).

Functional disorders and psychological medicine

There has been a deterioration in the mental health and emotional stability of the adolescent population over recent decades. Suicide is now one of the leading causes of death in young people aged 15–19, and anxiety and depression are a leading cause of disability and illness. There has been a significant rise in the prevalence of eating disorders (p. 1285), self-harming behaviours (p. 1276) and a noticeable cohort of adolescents that display their distress through physical somatic symptoms.

Traditional paediatric models of care have evolved to meet the changing needs of adolescents and young adults, and adult health-care models will be compelled to follow suit. There is a need for an integrated approach such that physical health needs are understood and treated alongside mental health needs, ideally co-located.

With respect to troublesome somatic symptoms, it is vital that clinicians do not mistakenly foster a false dichotomy and see young people as either having an organic (medically explained) diagnosis or a non-organic (medically unexplained) diagnosis where that might be taken to mean a psychological cause, but rather to recognise that the mind and body exist together and as such should be treated together. The roots of best practice when treating the complexities of any patient presenting with a mix of challenges to their health resulting in functional impairment, lie with the teachings of Sir William Osler, who considered that 'the good physician treats the disease, the great physician treats the patient who has the disease'. His perspective epitomised the need for a holistic approach – to treat and understand the patient first and foremost.

i 31.17 Prevalence of functional symptoms per specialty

Health domain	Prevalence of functional symptoms	Common presenting symptoms
Primary care/ family medicine	20%–30%	Fatigue, dizziness, pain, non-specific gastrointestinal symptoms without identifiable pathology
Gastroenterology	Up to 50%	Irritable bowel syndrome, functional dyspepsia. Symptoms might include pain, altered bowel habit without identifiable pathology
Neurology	20%–30%	Non-epileptiform seizures, functional movement disorders, chronic headache disorders without identifiable pathology
Rheumatology	10%–20%	Fibromyalgia, pain, fatigue, and cognitive symptoms without clear inflammatory or autoimmune markers
Cardiology	10%–15%	Chest pain, palpitations or other cardiovascular-like symptoms without structural heart disease, sometimes referred to as non-cardiac chest pain
Gynaecology	15%–20%	Chronic pelvic pain and some cases of dysmenorrhea, which do not have an identifiable cause
Psychiatry	Common, but difficult to quantify	Often functional disorders are a secondary diagnosis. Somatic symptom disorder and health anxiety are often managed in psychiatry settings

Functional disorders, also known as somatic symptom disorders or functional somatic syndromes, are conditions where patients experience symptoms without a clear structural or biochemical cause. These conditions are common in outpatient settings and can include issues like irritable bowel syndrome (IBS), chronic fatigue syndrome, fibromyalgia, and other conditions with unexplained physical symptoms (see Box 29.13). The proportion of outpatient visits for functional disorders varies by specialty (Box 31.17).

The challenge for clinicians meeting young adults with a possible functional disorder is that it is not unusual for a functional disorder to coexist with another diagnosis (for example, functional seizures can coexist with epilepsy, or irritable bowel syndrome with inflammatory bowel disease). Similarly, complex physical pathology may be found as a consequence of primary psychosocial pathology. Examples might include a young adult with profound physical disability associated with complex regional pain syndrome when even amputation can be considered to treat refractory pain, or young people requiring long-term enteral feeding as nutritional support for gastroparesis or feeding difficulties that originated from a functional disorder. These patients require management within a multidisciplinary team setting, and the lead clinician has to be skilled to manage the physical symptoms they are experiencing as well as contributing and responding to the wider psychosocial model of support that is necessary. Functional symptoms are often challenging to manage due to the lack of objective findings, requiring a multidisciplinary approach focused on symptom relief (where possible), improving overall function, patient education and addressing psychosocial factors.

Summary

Young people who have suffered long-term conditions during childhood represent a particularly high-risk group of patients as they progress through adolescence to become young and, finally, mature adults. They bring with them specific medical risks and complications related to their previous medical treatment, and knowledge of these is important to identify the long-term complications of the therapies to which they have been exposed. They are a patient group that can display complex illness behaviour. Understanding this and implementing an effective process for transition from paediatric to adult services can reduce the significant risks that these patients face in early adulthood. This group of patients is particularly vulnerable and prone to the combination of physical and psychosocial aspects of disease, and a multiprofessional approach to their assessment and management is essential. As they mature and develop more adult intellectual and emotional behaviour patterns, the risks to their health and well-being reduce. Patients in transition from adolescence to young adulthood can be a particularly challenging group to manage, but investment of time and effort at this stage of their lives can be extremely rewarding and can bring significant improvements in long-term health-related outcomes.

Multiple Choice Questions

31.1. When considering renal transplant rejection rates in children, kidney survival rates are better in:

A. Males
B. Older adolescents
C. Patients who have not been dialysed prior to transplantation
D. A parent donor rather than a sibling
E. A deceased donor under 2 years old rather than an older donor

Answer: C.

Five- and ten-year kidney survival rates have improved steadily in recent years, such that organ survival rates are now around 80% and 60%, respectively. Much of this has been delivered through improved immunosuppressive regimens, but there are patient-specific factors that also affect kidney survival. A worse outlook is seen in females, children of African and Caribbean origin and older adolescents in whom adherence is less good and transition to adult services is a negative factor. Kidney survival rates in general are better for living rather than deceased donors, but children rarely have brothers or sisters (some of whom are HLA identical) old enough to be an organ donor; as a result, most living donated allografts are from a parent, who is an obligate one haplotype match. Optimal HLA matching is important to minimise sensitisation, particularly for young recipients who will need retransplantations in later life. The best 5-year graft survival (90%) in paediatric patients is seen in patients who received a pre-emptive transplant or after short-term dialysis (<45 days). The poorest graft survival (52%) is in adolescent patients transplanted after long-term dialysis (>2.2 years). Kidneys from the youngest deceased donors have the poorest survival rates, although conversely, younger recipients tend to have improved renal transplant survival overall compared to older children.

31.2. Many children with long-term conditions (such as inflammatory bowel disease, the arthritides or connective tissue disorder, nephrotic syndrome, cystic fibrosis, or transplantation) have been taking long-term glucocorticoids. When considering adverse drug reactions (ADRs), important issues to consider include:

A. 20% of patients will have a reduction in skeletal growth/final adult height – females being more significantly affected than males
B. 20% of patients develop Cushingoid features with long-term glucocorticoid use – but low-dose glucocorticoids are not associated with this risk
C. Children and young people have lower rates of mood and behaviour changes with glucocorticoid therapy than adults
D. 25% of patients have biochemical evidence of hypothalamic–pituitary axis (HPA) suppression and this predisposes them to viral infections
E. Half of all glucocorticoid-related deaths are due to infection, and varicella zoster is the single commonest causative organism in patients who die from steroid-related sepsis

Answer: E.

Treatment with long-term glucocorticoids carries significant long-term health risks, and these are particularly important for children who have been exposed to glucocorticoids for long periods of time during their childhood. Up to 20% experience reductions in growth – males are more significantly affected than females and there is an average significant weight gain of 5%–10%. Children and young people seem more vulnerable to mood and behaviour side-effects than adults, and steroid psychosis can be a particular problem in adolescents. Sixty percent of patients on long-term glucocorticoids have biochemical evidence of HPA suppression and this makes them particularly vulnerable to infections. Varicella is the commonest cause of sepsis-related death, and sepsis is the most serious of the described ADRs.

31.3. When considering the initiation of transition planning, which of the following is true?

A. It is sensible to plan this to coincide with the end of the young person's time in full-time education
B. Transition planning is better delayed in patients with learning difficulties to aid their understanding of the process
C. Transition planning should begin between 11 and 12 years of age in all young people with a long-term condition who are likely to need treatment in adulthood
D. Transition planning should be started earlier in children with more severe conditions
E. It is best to involve adult clinicians in shared clinical care as early as possible in the transition process

Answer: C.

Transition planning should be initiated at around 12 years of age in all patients who are likely to have ongoing health needs in adulthood, regardless of disease severity, the presence of learning difficulties or even the patient's willingness to consider transfer to another provider. The face-to-face consultation with adult colleagues and shared clinical decision-making is one of the final steps before full transfer to adult services.

31.4. Obesity is a growing problem in paediatrics and adolescence. When prescribing drugs for patients who are overweight, which of the following is true?

A. When prescribing drugs on a dose per kilogram basis, it is important that the actual weight for height is used when calculating drug dosages, even if the calculated dose exceeds the recommended adult dose
B. When prescribing drugs on a dose per kilogram basis, it is important that the optimal weight for height is used when calculating drug dosages and not to exceed the recommended adult dose
C. Adult drug dosages can safely be used in male and female children above 16 years since growth has stopped by then
D. Hydroxychloroquine can be prescribed using either optimal or actual body weight in adolescents who are clinically obese
E. Obesity in adolescents is generally defined to be present when the actual body weight is more than 30% greater than optimal body weight

Answer: B.

Many paediatric prescribing regimens use a dose per kilogram calculation to avoid overdosing. However, in obese young people (those in whom actual weight is $>20\%$ ideal weight), this can result in a risk of overdosing. Accordingly, ideal body weight rather than actual body weight should be used when calculating drug dosages. Centile charts can be used to calculate ideal body weight in growing children based on age and height. It should be noted that height and weight continue to increase through the late teenage years in boys, whereas in girls, both tend to stabilise around the age of 16 years. Whether or not the patient is obese, it is important to ensure that the actual dose prescribed does not exceed the standard adult dose.

31.5. A 19-year-old male presented to your hospital after a witnessed out-of-hospital cardiac arrest. He was previously fit and well but resuscitation was not successful and the clinical diagnosis was of sudden cardiac death (SCD). The family are seeking advice about the risks for the wider family; there are two surviving siblings, aged 16 and 12 years old. Which of the following is true:

A. The cause of death can be identified in 60% of cases once histopathology results are available
B. The siblings need to undergo cardiac screening
C. First-degree relatives should undergo ECG, echocardiogram, exercise tolerance test, Holter monitor, cardiac MR and adrenaline challenge
D. If the postmortem is normal, a primary arrhythmia syndrome is the most likely diagnosis. The majority of these are inherited in an autosomal dominant manner
E. It is important to diagnose hypertrophic cardiomyopathy (HCM) as this has genetic implications and treatment with propranolol modifies disease progression

Answer: D.

Sudden cardiac death in the young is a devastating event and generates significant familial anxiety. If postmortem examination is normal then inherited arrhythmia is the most likely diagnosis (such as long QT syndrome, Brugada syndrome). Genetic testing in the proband is helpful, but first-degree family members should also undergo detailed cardiological assessment including ajmaline challenge to exclude Brugada syndrome. The diagnostic yield is much higher if parents are included as well as siblings – extending the investigations to surviving family members increases the chances of reaching a definitive diagnosis to 40% even in cases where postmortem examination is normal. HCM could be diagnosed at postmortem examination and is relatively common, affecting 1 in 500 people. It too has autosomal dominant inheritance. Treatment with β-adrenoceptor antagonists (β-blockers) reduces the incidence of sudden death but has not been shown to alter progression of hypertrophy. An implantable cardiac defibrillator (ICD) is considered the only effective strategy for prevention of arrhythmic SCD in patients with HCM.

History

Approach

- Find a quiet area free from external distractions
- Ensure the patient can hear (if hearing aids are needed, ensure they are working)
- Slow down the pace
- Carry out a full systematic enquiry

Content

- Establish the person's goals and expectations of treatments
- Medication history, including adherence, recent changes to medications and any non-prescribed drugs or supplements
- Past medical history, even from many years previously
- Establish usual function – change in function is often a sign of illness
- Ask specifically about: mobility, continence, cognition, self-care

Collateral

- Obtain a collateral history from a suitable informant (relative, care-giver or family doctor)
- Ask about care-giver stress

Social assessment

Home circumstances

- Living alone, with another person or in a care home
  Stairs, access to toilet, adequate heating

Activities of daily living (ADLs)

- Tasks for which help is needed:
  Basic ADLs: bathing, dressing, walking
  Extended ADLs: shopping, cooking, housework

Social support

- Informal assistance: relatives, friends, neighbours
- Formal assistance: social care, home help, meals on wheels

Examination – general points

- Thorough and systematic
- Tailored to the patient's stamina and ability to cooperate, may need to be performed in stages
- Includes cognitive function, gait, pressure areas, hearing and vision
- Initial assessment is screening rather than diagnostic; for example, screening visual acuity can be performed using different sizes of print in a newspaper
- Maintains safety; for example, ensure you have appropriate assistance before mobilising an unwell older adult for the first time
- Includes assessment of risk of future events; for example, assessing skin for risk of pressure sores, assessing gait and balance for risk of falls

Cognitive screening

- Sensitively, enquire about level of education and ability in reading and writing.
- Maximise cognitive abilities, ensure glasses are worn, hearing aids turned on.
- Screen for delirium using a validated tool such as 4A Test (4AT). If the person struggles with this test, then more detailed direct testing may not be possible.
- Use a multidomain cognitive assessment validated for the language of the person being tested (e.g. Montreal Cognitive Assessment, see Ch. 29).
- Complement the cognitive assessment with collateral information; use a structured questionnaire such as the AD8.
- Change in cognition is important; look for results of any previous cognitive tests in medical records.

④ Assessment for postural hypotension

- Have the person supine and relaxed for at least 5 minutes.
- Measure blood pressure with manual sphygmomanometer.
- Keep the sphygmomanometer cuff on the person's arm.
- Stand the person up rapidly but safely (in some cases lying to sitting measures may be needed).
- Check standing blood pressure immediately and then at 1, 2, 3 minutes.
- Ask about symptoms with each blood pressure check.
- A fall of > 20 mmHg systolic or > 10 mmHg diastolic defines postural hypotension, but important symptomatic drops may be seen with lesser falls in blood pressure.

④ Assessment and prevention of pressure ulcers

Pressure ulcers are tissue damage resulting from forces that compromise the blood supply to the area. Older adults often have multiple risk factors for pressure ulcers which include:

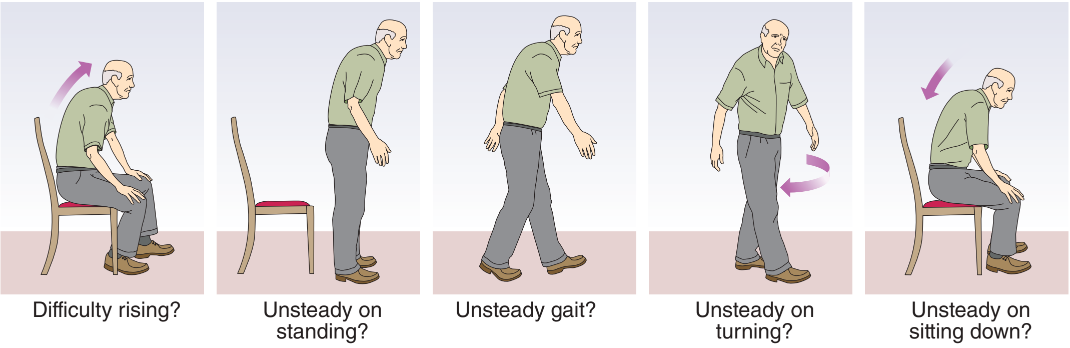
- Cognitive impairment
- Critical illness
- Elder abuse or neglect
- Incontinence
- Limited mobility
- Loss of sensation (for example peripheral neuropathy)
- Poor nutrition

Older adults admitted to hospital should have their risk of pressure ulcer assessed including a thorough examination of the skin.

Those at risk should be encouraged to change position frequently; if they struggle to reposition themselves then assistance and use of pressure redistributing devices will be needed.

⑭ Get up and go test

To assess gait and balance, ask the patient to stand up from a sitting position, walk 3 m, turn and go back to the chair. This can be timed and usually takes less than 12 seconds. However, observed performance is more important than precise timing.



Difficulty rising?
Unsteady on standing?
Unsteady gait?
Unsteady on turning?
Unsteady on sitting down?

Demographic change has meant that older people now represent the core practice of medicine. A knowledge of the effects of ageing, and the associated clinical problems, is therefore essential for all clinicians. The older population is diverse; a substantial proportion of 90-year-olds enjoy an active healthy life, while some 70-year-olds are severely disabled by chronic disease. The terms 'chronological' and 'biological' ageing have been coined to describe this phenomenon. In the context of medical care, biological age is the important factor.

An important consideration in health care of older adults is frailty – where physiological capacity is so reduced that even minor illness has serious consequences. Management in frailty differs from that in a robust younger adult in fundamental ways. Disability and comorbidities can complicate both assessment and treatment, and acute illness may present with non-specific symptoms. A broad knowledge of medicine is required, as diseases in any, and often many, organ systems must be managed at the same time. Finally, the person's expectations and goals of treatment may differ from younger adults, and these should be established as early as possible.

Older people are under-represented in clinical trials, with limited high-quality evidence on which to base practice. However, some interventions have a compelling evidence base, such as the process of Comprehensive Geriatric Assessment.

Demography

Improvements in health care, lifestyle and public health measures have resulted in prolonged life expectancy across the world. Life expectancy gains are seen even in old age; women aged 80 years can expect to live for a further 10 years. As a result, the ratio of people of working age to people over retirement age has substantially increased. For example, the proportion of people aged over 65 in India has increased by 35.5%, almost twice the rate of growth of the general population. The rate of population ageing is faster in developing countries and so there will be less time to adjust to its impact. Since young people support older members of the population both through taxation and pension contributions, the consequences of population ageing are far-reaching. However, it would be wrong to consider older adults only as a societal burden; many older people support the younger population, for example through care-giver roles. Preferred terms for older adults that avoid negative connotations and ageism are described in Box 32.1.

Rates of disability and chronic illness rise sharply with ageing and have a major impact on health and social services. In the UK, the reported prevalence of a chronic illness sufficient to restrict daily activities is around 25% in those aged 50–64, but 66% in men and 75% in women aged over 85.

32.1 Preferred terminology

The importance of using correct language is increasingly recognised. Certain terms that were previously used to describe older adults may no longer be acceptable to this population. Examples are given below.

Discouraged term	Rationale for change	Preferred term
The elderly	Vague, reductionist, could contribute to negative perceptions of ageing	Older adults
Geriatric	Controversial; the clinical discipline continues as geriatric medicine, but the label geriatric for people is felt to be ageist	Older adults
XX patient; for example, diabetic patient	Felt to be reductionist and can be imprecise, not all people living with a condition wish to be defined by it and many self-manage their conditions. 'Patient' is now reserved for those in hospital or receiving direct medical care at the time	Person living with diabetes
Senile	Vague, negative connotations	Cognitive impairment

Functional anatomy and physiology

Biology of ageing

Ageing can be defined as the accumulation of random molecular defects that build up over the life-course. Despite multiple repair and maintenance mechanisms, eventually these defects result in functional impairments of tissues and organs. Genes that contribute to ageing include those involved in regulation of DNA repair, telomere length, and insulin signalling. However, genetic factors only account for around 25% of the variance in human lifespan, with lifestyle and environmental factors more important determinants.

At a cellular level, production of reactive oxygen species is thought to play a major role in ageing. These molecules cause oxidative damage at a number of targets (Box 32.2). There is evidence in some organisms that the variation in biological ageing is partly mediated by insulin signalling pathways and chronic inflammation, so called inflamm-ageing.

Physiological changes of ageing

Physiological features of disease-free, normal ageing have been described (Fig. 32.1). However, ageing is so often associated with concomitant disease that the use of the term 'normal' is debatable. Age-related changes alone are usually not enough to interfere with organ function, but reserve capacity can be significantly reduced with implications for response to an external stressor like disease.

Ageing is characterised by substantial inter-individual variation in function. Thus, each person must be assessed individually, and the same management cannot be applied unthinkingly to all people of a certain age.

Core concepts in older adults

Frailty, disability and multimorbidity

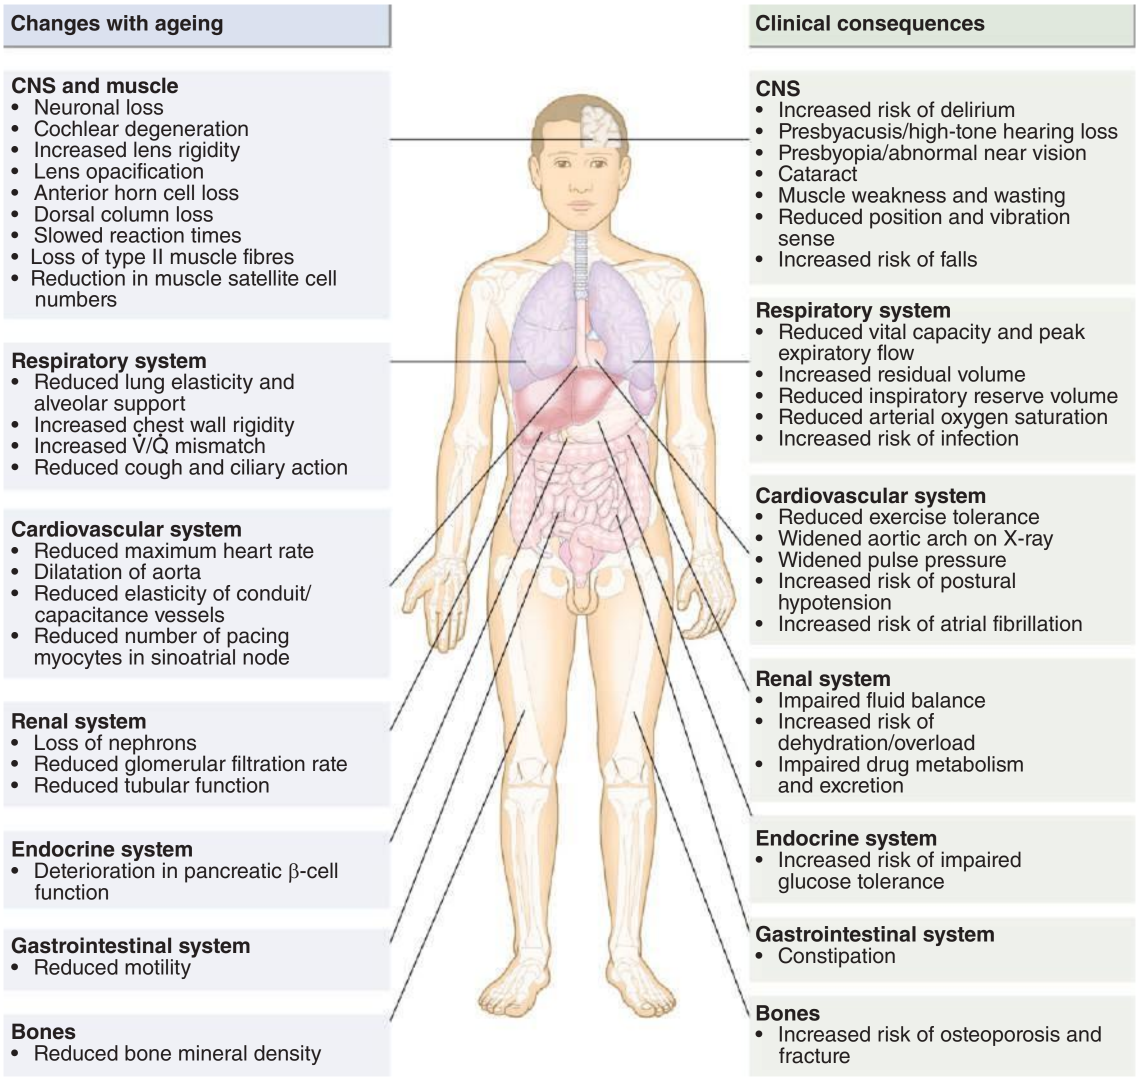
Frailty

Frailty is defined as the inability to withstand minor stresses because of reduced functional reserve across organ systems. Thus, in frailty even a trivial illness may result in organ failure and death (Fig. 32.2). The term 'frail' has often been used rather vaguely, sometimes to justify a lack of adequate investigation and intervention in older people. Frailty research has substantially increased in the last decades and we now have a better understanding of its implications and management.

There are various complementary approaches to the assessment of frailty (Box 32.3). The cumulative deficit model counts the number of age-related symptoms, signs, diagnoses and test abnormalities. If this count is compared against a pre-defined list of issues, then a frailty

32.2 Structural damage contributing to ageing

- *Nuclear chromosomal DNA:* mutations and deletions ultimately lead to aberrant gene function and potential for malignancy.
- *Telomeres:* these structures at the ends of chromosomes shorten with each cell division. When sufficiently eroded, cells stop dividing. This 'biological clock' prevents uncontrolled cell division and cancer. Telomeres are particularly shortened in patients with premature ageing due to progeria.
- *Mitochondrial DNA:* mutations and deletions resulting in reduced cellular energy production and ultimately cell death.
- *Proteins:* glycosylation due to spontaneous reactions between proteins and sugars damages structure and function.



Changes with ageing
CNS and muscle
• Neuronal loss
• Cochlear degeneration
• Increased lens rigidity
• Lens opacification
• Anterior horn cell loss
• Dorsal column loss
• Slowed reaction times
• Loss of type II muscle fibres
• Reduction in muscle satellite cell numbers
Respiratory system
• Reduced lung elasticity and alveolar support
• Increased chest wall rigidity
• Increased V̇/Q̇ mismatch
• Reduced cough and ciliary action
Cardiovascular system
• Reduced maximum heart rate
• Dilatation of aorta
• Reduced elasticity of conduit/capacitance vessels
• Reduced number of pacing myocytes in sinoatrial node
Renal system
• Loss of nephrons
• Reduced glomerular filtration rate
• Reduced tubular function
Endocrine system
• Deterioration in pancreatic β-cell function
Gastrointestinal system
• Reduced motility
Bones
• Reduced bone mineral density
Clinical consequences
CNS
• Increased risk of delirium
• Presbyacusis/high-tone hearing loss
• Presbyopia/abnormal near vision
• Cataract
• Muscle weakness and wasting
• Reduced position and vibration sense
• Increased risk of falls
Respiratory system
• Reduced vital capacity and peak expiratory flow
• Increased residual volume
• Reduced inspiratory reserve volume
• Reduced arterial oxygen saturation
• Increased risk of infection
Cardiovascular system
• Reduced exercise tolerance
• Widened aortic arch on X-ray
• Widened pulse pressure
• Increased risk of postural hypotension
• Increased risk of atrial fibrillation
Renal system
• Impaired fluid balance
• Increased risk of dehydration/overload
• Impaired drug metabolism and excretion
Endocrine system
• Increased risk of impaired glucose tolerance
Gastrointestinal system
• Constipation
Bones
• Increased risk of osteoporosis and fracture

Fig. 32.1 Features and consequences of normal ageing.

index can be calculated, where the numerator is the number of deficits present in an individual and the denominator is the total number of deficits assessed. The phenotypic approach is based on a series of common features associated with poor outcomes, such as exhaustion and reduced strength. Finally, the syndromic approach recognises that patients with frailty tend to respond to disease in stereotyped ways. A list of presentations that are markers of underlying frailty was first described by Sir Bernard Isaacs in his text on 'Geriatric Giants'. In clinical practice, clinicians can often recognise frailty based on initial assessment. Frailty scales, such as that described by Rockwood, offer guidance and illustration to allow standardisation and categorisation of frailty into an ordinal scale (Fig. 32.3).

Older people with frailty benefit from a clinical approach that addresses both acute illness and underlying loss of reserves. It may be possible to prevent further loss of function through early intervention. For example, an older adult with myocardial infarction may benefit from cardiovascular secondary prevention medications, but may benefit even further from an exercise programme that improves strength, balance and aerobic capacity.

Disability

Disability is an umbrella term for describing loss of function that results from complex interactions between health, environmental and personal factors. The World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF) provides a framework for understanding this concept at the levels of basic body structure and function, activity limitations (previously called disability) and participation in society (previously called handicap) (Fig. 32.4). Care of the older adult should seek not only to cure or limit disease but also to minimise the resulting disability. Given the multifaceted nature of disability, this often requires a team approach with expertise in differing areas.

Multimorbidity

Multimorbidity describes a state where multiple health conditions coexist in an individual. There is no consensus on the total number of conditions that should define multimorbidity, and with increasing age, accumulation of chronic conditions is almost inevitable. Regardless of the definition used, multimorbidity is a driver for future disability, hospitalisation and death. A related concept is polypharmacy, where multiple medications are used to treat each chronic disease.

Traditional health-care systems are poorly equipped to manage multimorbidity. When each disease is dealt with by a separate team of specialists, this places a high burden on the patient and can lead to inefficiency, replication and sometimes mutually incompatible approaches to the management of each disease.

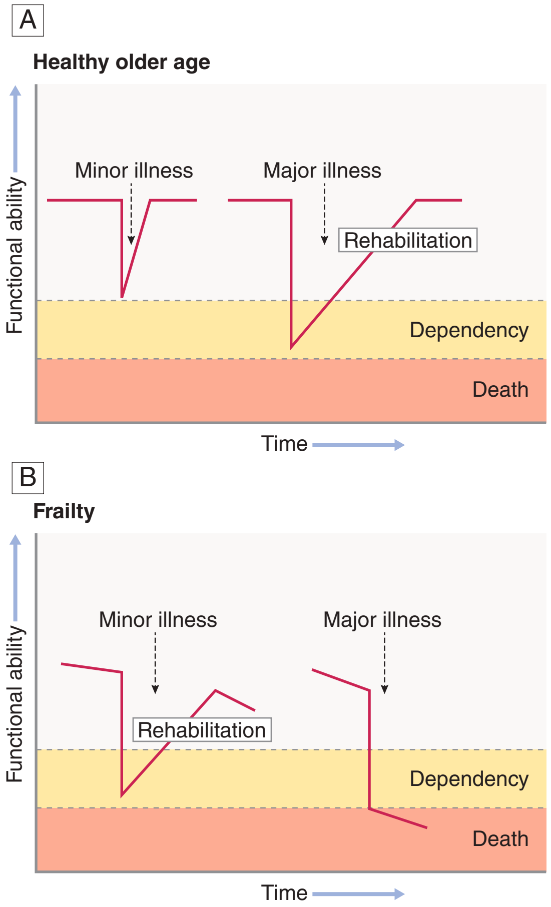


Fig. 32.2 **Differing responses to illness in health and frailty.** Note that in frailty the response to illness is more severe and even minor illness can cause functional issues requiring rehabilitation.

32.3 Two approaches to assessment of frailty

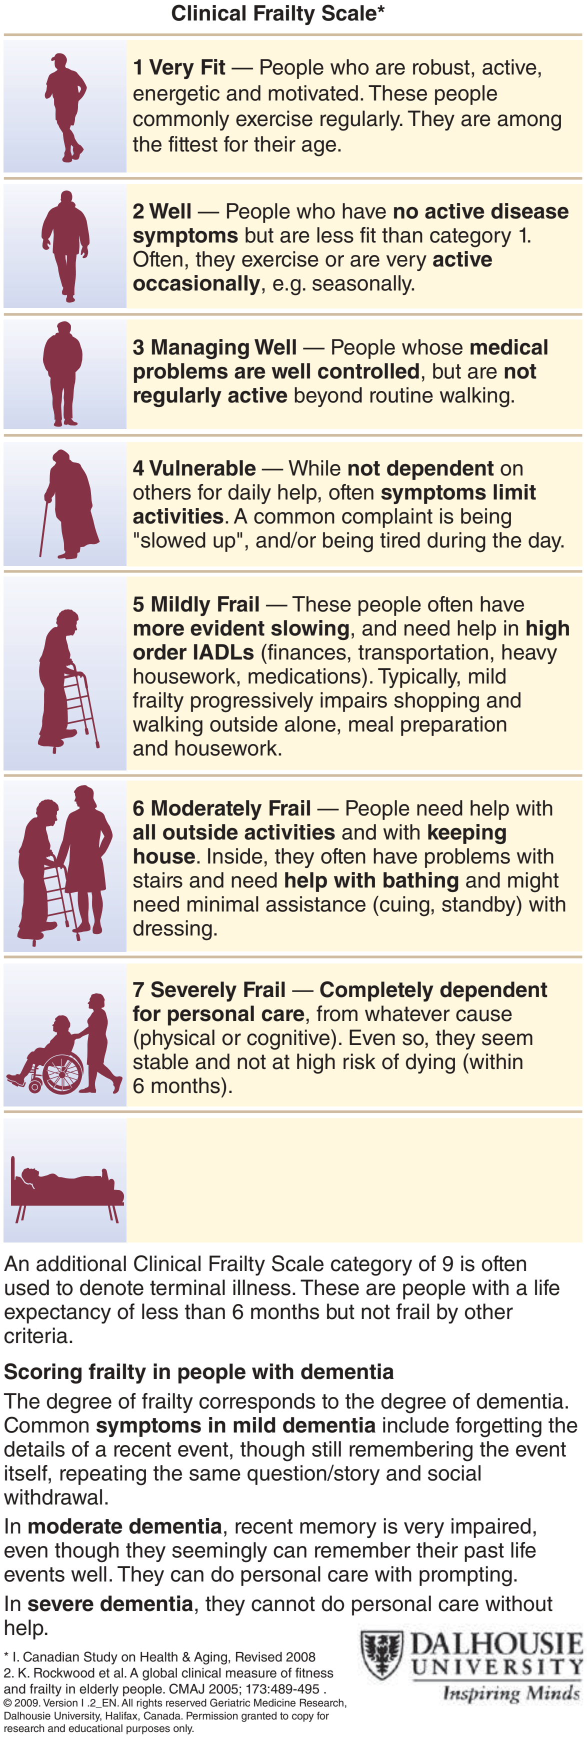
Fried frailty phenotype

- Weak hand grip strength
- Slow walking speed
- Self-reported exhaustion
- Physical inactivity
- Unintentional weight loss

Frailty syndromes

- Immobility (decline in function)
- Instability (falls)
- Incontinence
- Intellectual impairment (dementia, delirium)
- Iatrogenic disease and social isolation

It is important to understand the difference between frailty, disability and multimorbidity. These concepts frequently coexist, but they are distinct. Disability indicates established loss of function while frailty indicates increased vulnerability to loss of function. Disability may arise from a single pathological event (such as a stroke) in an otherwise robust individual. When frailty and disability coexist, function may deteriorate markedly even with minor illness, to the extent that the patient can no longer manage independently. Multimorbidity is also not equivalent to frailty or disability; it is possible to have several diagnoses without major impact on homeostatic reserve or function.



Clinical Frailty Scale*

1 Very Fit — People who are robust, active, energetic and motivated. These people commonly exercise regularly. They are among the fittest for their age.

2 Well — People who have **no active disease symptoms** but are less fit than category 1. Often, they exercise or are very **active occasionally**, e.g. seasonally.

3 Managing Well — People whose **medical problems are well controlled**, but are **not regularly active** beyond routine walking.

4 Vulnerable — While **not dependent** on others for daily help, often **symptoms limit activities**. A common complaint is being "slowed up", and/or being tired during the day.

5 Mildly Frail — These people often have **more evident slowing**, and need help in **high order IADLs** (finances, transportation, heavy housework, medications). Typically, mild frailty progressively impairs shopping and walking outside alone, meal preparation and housework.

6 Moderately Frail — People need help with **all outside activities** and with **keeping house**. Inside, they often have problems with stairs and need **help with bathing** and might need minimal assistance (cuing, standby) with dressing.

7 Severely Frail — **Completely dependent for personal care**, from whatever cause (physical or cognitive). Even so, they seem stable and not at high risk of dying (within 6 months).

An additional Clinical Frailty Scale category of 9 is often used to denote terminal illness. These are people with a life expectancy of less than 6 months but not frail by other criteria.

Scoring frailty in people with dementia

The degree of frailty corresponds to the degree of dementia. Common **symptoms in mild dementia** include forgetting the details of a recent event, though still remembering the event itself, repeating the same question/story and social withdrawal.

In **moderate dementia**, recent memory is very impaired, even though they seemingly can remember their past life events well. They can do personal care with prompting.

In **severe dementia**, they cannot do personal care without help.

Fig. 32.3 **The Clinical Frailty Scale.** (IADLs = instrumental activities of daily living)

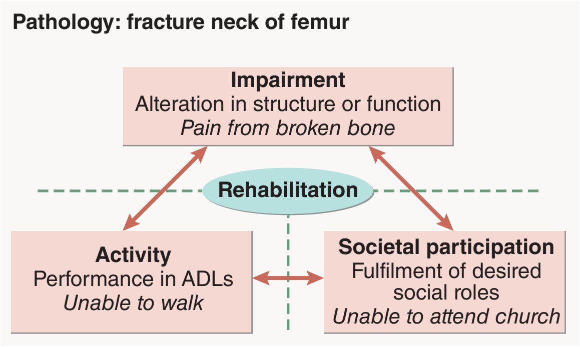

Fig. 32.4 The WHO International Classification of Functioning, Disability and Health (ICF). Note that the various levels of function interact, and relationships are potentially bidirectional. For example, while a broken bone (impairment) may directly limit walking (activity), a maladaptive, antalgic gait (activity) may also impair healing (impairment). Pathology may directly and indirectly have an impact at all levels of function. This has implications for treatment, and a rehabilitation strategy will need to target all levels of function. (ADLs = activities of daily living)

Rehabilitation

Rehabilitation aims to improve the ability of people of all ages to perform activities that are important to them. Rehabilitation is often needed in older adults for two reasons: acute illness can be associated with decline in functional ability and with increasing age comes increasing risk of chronic disabling conditions such as osteoarthritis or stroke.

The rehabilitation process

Rehabilitation is a holistic, problem-solving process focused on improving the patient's physical, psychological and social function. It entails:

- *Assessment*. The nature and extent of the patient's problems can be identified using the WHO ICF (see Fig. 32.4). Doctors tend to focus on health conditions and impairments, but patients are often more concerned with daily activity and ability to participate in society. Specific assessment scales, such as the Barthel Index of basic activities of daily living (ADLs) (Box 32.4), are useful to quantify function but additional assessment is needed to determine the underlying causes and interventions required.
- *Goal-setting*. Goals should be specific to the patient's problems, should be realistic, and agreed between the patient and the rehabilitation team.
- *Intervention*. This includes treatments needed to achieve goals and to maintain health and quality of life. Interventions may include hands-on treatment by therapists using a functional, task-orientated approach, education, training and psychological support. The intervention should be individualised, according to the patient's goals and abilities.
- *Re-assessment*. There is ongoing re-evaluation of the patient's function and progress by the rehabilitation team, the patient and the care-giver. Interventions may be modified as a result.

Multidisciplinary team working

Effective rehabilitation requires a multidisciplinary team approach; core members of the team are described in Box 32.5. Others may also be involved, such as audiometry to correct hearing impairment, podiatrists for foot problems, and orthotics where prosthesis or splinting is required. Good communication and mutual respect are essential. Regular team meetings allow agreement on rehabilitation goals, evaluation of progress and planning for discharge. Rehabilitation is *not* when the doctor orders 'physiotherapy' or 'a home visit' and takes no further role.

Rehabilitation outcomes

There is evidence that rehabilitation improves functional outcomes and reduces mortality in older people following acute illnesses like stroke and hip fracture. These benefits accrue from complex multicomponent interventions, but occupational therapy to improve personal ADLs and individualised exercise interventions have been shown to be effective in improving functional outcome in their own right.

32.4 How to assess basic activities of daily living using the Modified Barthel Index*

	Independent	Needs help	Unable to do
Mobility	15	10 5 wheelchair	0
Stairs	10	5	0
Transfers (bed to chair)	15	10 minor help 5 major help	0
Continent bladder	10	5 occasional incontinence	0
Continent bowels	10	5 occasional incontinence	0
Grooming	5	0	0
Toilet use	10	5	0
Feeding	10	5	0
Dressing	10	5	0
Bathing	5	0	0

*The 100-point version is illustrated. If a person is completely unable to perform a task, the score is zero. The total score reflects the degree of dependency.

32.5 Multidisciplinary team (MDT) roles

Team member	Activity assessed and promoted
Physiotherapist	Mobility, balance and upper limb function
Occupational therapist	ADLs, home environment and care needs
Dietitian	Nutrition
Speech and language therapist	Communication and swallowing
Social worker	Care needs and discharge planning
Nurse	Self-care, feeding, continence, skin care
Doctor	Diagnosis and management of medical problems

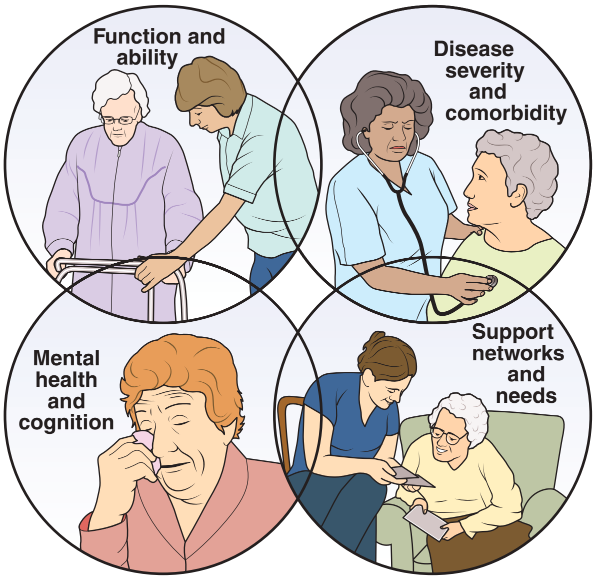
(ADLs = activities of daily living)

Investigation and management

Comprehensive Geriatric Assessment

One of the most powerful tools in the management of older people is Comprehensive Geriatric Assessment (CGA) (Fig. 32.5). The term assessment is in fact a misnomer; CGA is not merely assessment, but a dynamic, iterative process of identifying and managing all factors affecting the health and well-being of an older person. The process should begin as soon as possible following acute illness or functional decline. The outcome should be a coordinated, goal-driven management plan that not only addresses the acute presenting problems but also seeks to improve the patient's overall health and function.

The CGA approach was pioneered by Dr Marjory Warren in the 1930s. Her comprehensive assessment and rehabilitation of supposedly incurable, bedridden older people revolutionised the approach of the medical profession to frailty and laid the foundations for the modern specialty of geriatric medicine. There is high-quality evidence that CGA reduces death or deterioration and increases the chances of living independently at home. The process works best when delivered by a dedicated multidisciplinary team on a specialist inpatient unit.



Function and ability
Disease severity and comorbidity
Mental health and cognition
Support networks and needs

Fig. 32.5 The core elements of Comprehensive Geriatric Assessment.

Decisions about investigation and treatment

Management plans in older adults need to be mindful of the implications of frailty, disability and multimorbidity. However, old age alone should not preclude potentially useful treatments. Change in function should never be dismissed as due to age alone. For example, it would be wrong to supply a wheelchair to a patient struggling to mobilise, when simple tests would have revealed treatable osteoarthritis and angina.

Does the patient want this investigation?

Older people may have strong views about the extent of investigation and the treatment they wish to receive, and these should be sought from the outset. A key issue is to establish what the patient wants from health care. Many older people do not desire prolongation of life; rather, they aspire to maintain physical function, gain relief from symptoms and preserve the ability to live independently. It can be useful to proactively document the person's wishes, so that difficult decisions around ceilings of care do not have to be made in an emergency.

While the wishes of the patient should inform all aspects of care, there can be situations where a person is unable to sufficiently understand the situation or communicate their opinions. Assessment of mental capacity should be part of every clinical consultation, but is especially important in older adults where acute and chronic illness can impair decision-making. Differing health-care systems have differing legislation around assessment of capacity, and management when the patient is unable to make an informed decision. However, all agree that the assessment of capacity should be clearly documented and should be reassessed if there is a clinical change, for example a resolving delirium. Every effort should be made to maximise the patient's ability to participate in decision-making, and this may require input from other team members such as speech and language therapy.

Family or care-givers may be able to give information on views previously expressed or on what they believe the patient would have wanted under the current circumstances. However, families should never be made to feel responsible for difficult decisions. Advance directives or 'living wills' allow people to document their views and are used if they are no longer able to make or communicate these decisions. However, advance directives and family wishes cannot authorise a clinician to do anything that, in their professional opinion, is not clinically appropriate.

Will the investigation be feasible?

Does this patient have the capacity to tolerate the proposed investigation? For example, do they have the aerobic capacity to undergo bronchoscopy? Will delirium prevent them from remaining sufficiently still to allow magnetic resonance imaging (MRI) scanning of the brain? Increasing frailty, disability and comorbidity make it less likely a patient will be able to withstand an invasive intervention.

Will the investigation alter management or outcomes?

Would the patient be fit for, or benefit from, the treatment that would be indicated if investigation proved positive? When a patient with severe heart failure and a previous disabling stroke presents with a suspected cancer on chest X-ray, detailed staging may not be appropriate if they are not fit for intervention. On the other hand, if the same patient presented with dysphagia, investigation of the cause could be important, as this may facilitate endoscopic treatment to palliate an obstructing oesophageal lesion and allow resumption of oral diet.

It is important to consider whether interventions that might be considered standard of care for younger people are likely to be beneficial in older people living with frailty. For example, while guidelines may recommend tight glycaemic control in diabetes mellitus, such treatment may not accord with the wishes of a patient in a care home who finds regular blood tests distressing, or who is more worried about immediate hypoglycaemia than future vascular complications.

Presenting problems

Characteristics of presenting problems in old age

The traditional single-organ, single-disease paradigm is rarely helpful in older people. Most presentations are multifactorial, with a social and environmental aspect, and there is rarely a single unifying diagnosis. The diagnostic formulation is more commonly a list of problems, some acute and some chronic. There are certain features of illness presentation that are particular to older patients.

Late presentation

Many people accept ill health as a consequence of ageing and may tolerate symptoms for lengthy periods before seeking medical advice. Comorbidities may also contribute to late presentation. For example, in a patient whose mobility is limited by stroke, angina may only present when coronary artery disease is advanced, as the patient has been unable to exercise sufficiently to cause symptoms at an earlier stage.

Atypical presentation

The classical presentations of diseases are rarely seen in frailty. Infection may present with delirium and no clinical pointers to the organ system affected. Myocardial infarction may present as weakness and fatigue, without chest pain or dyspnoea. Cognitive impairment may limit the patient's ability to give a history of classical symptoms.

Acute illness and changes in function

A change in functional ability is a common presentation of illness in frailty. Often labels such as 'failure to cope' and 'off feet' are used, but these are *not* diagnoses, and should not prevent a comprehensive assessment for underlying precipitants. It is vital to establish the person's usual level of functioning and the chronicity of any change. Collateral information from a relative or care-giver can be useful.

Multiple pathology

Presentations in older patients have diverse differential diagnoses, and various contributory problems, both acute and chronic, can coexist. For example, a patient may have recurrent falls because of osteoarthritis of the knees, drug-induced postural hypotension and poor vision from cataracts. All these factors must be addressed to prevent further falls.

Potential for prevention

The adage 'prevention is better than cure' is particularly relevant in older age. Vaccination programmes for seasonal influenza, COVID-19, pneumococcus and herpes zoster can all reduce incidence, severity or complications from the relevant infections. Older adults living with frailty or other risk factors should be encouraged to engage with vaccination programmes. In many health-care systems, screening programmes for cancers and other conditions are offered as early detection may allow for more treatment options and greater chance of cure.

The heterogeneity in the ageing phenotype is predominantly driven by environmental and lifestyle factors, such as poverty, exercise and cigarette smoking. By implication, a healthy lifestyle should be encouraged even in older age.

Although admission to hospital is often required in acute illness, the traditional hospital environment is not always suited to the needs of older adults, especially those with physical or cognitive frailty. Various models of care to prevent hospital admission have been described including use of day hospital or intermediate care facilities and providing care in the person's home. These approaches are popular with older adults, and may improve outcomes in some situations, but there must be easily accessible pathways into the acute hospital where a change in clinical condition requires this.

Approach to presenting problems in old age

For the sake of clarity, the common presenting problems are described individually but, in reality, older patients often present with several presentations at the same time. Syndromes such as falls or incontinence represent a final common pathway that is the result of a variety of insults. For most presenting problems in old age, the clinician has to search for and treat any acute illness as well as identifying and reversing predisposing risk factors. The initial approach to assessment is often less focused than would be typical in a younger, robust patient. To further complicate the assessment, results of initial investigations may be outside normal ranges but not necessarily indicative of an acute issue that needs treatment (Boxes 32.6 and 32.7).

Falls and collapse

A commonly used definition describes a fall as an unexpected event in which the person comes to rest on the ground without known loss of consciousness. Around 30% of people over 65 years of age fall each year, and this figure rises to more than 40% in those aged over 80.

Important aspects in the assessment of falls include an assessment of the mechanism, risk factors and consequences.

Mechanism

Falls are one of the classic presentations of acute illness in frailty. The reduced reserves in older people's neurological function mean that they are less able to maintain their balance when challenged by an acute illness, while loss of muscle structure and function (sarcopenia) has an impact on biomechanics. It can be useful to distinguish between an 'explained' and 'unexplained' fall. There may be a clear account of an accident, for example a trip on uneven ground. Risk factors for falls should be considered in the history and examination (Box 32.8). Careful assessment of the patient's gait may provide important clues to an underlying diagnosis (Box 32.9). A proportion of older people with unexplained falls have, in fact, had a syncopal episode. A collateral history from a witness is crucial as people who lose consciousness do not always remember having done so. As differentiating syncopal and non-syncopal falls is challenging, all patients who fall should have a 12-lead electrocardiogram and assessment for postural hypotension (see p. 1339).

Management

Older adults who have fallen more than once in the past year and those who are unsteady during a 'get up and go' test (see p. 1339) require further assessment and may benefit from multidisciplinary intervention. Evidence-based interventions to prevent or reduce recurrent falls involve a multifactorial, multidisciplinary approach (Box 32.10). People at low or moderate risk of falls benefit most from balance and strength training

32.6 Screening investigations for acute illness

- Full blood count
- Urea and electrolytes, liver function tests, calcium and glucose
- Chest X-ray
- Electrocardiogram
- C-reactive protein: useful marker for infection or inflammatory disease
- Procalcitonin: inflammatory marker more specific to bacterial infection
- Lactate: non-specific marker of severe illness
- Urinalysis: although a positive urine dip is not synonymous with urinary tract infection
- Blood cultures if pyrexial

32.7 Interpreting test results in older adults

Test result outside normal range	Interpretation in older adults
Autoantibodies, e.g. antinuclear antibodies	Positive results at low titre are often of no significance, especially if taken at a time of acute illness
Asymptomatic bacteriuria	Bacteriuria is common in older adults; indeed the majority of female care-home residents have bacteriuria. Treatment should target symptoms of infection
D-dimer	Bruising, infection and inflammation can all cause an increase in D-dimer; the test is most useful when normal as it makes substantial venous thrombosis unlikely
Hyponatraemia	Can be chronic and often relates to prescribed medication; mild, unchanged hyponatraemia in a person taking culprit medications may not need extensive investigation
Thyroid-stimulating hormone (TSH)	Often abnormal during illness; normal ranges may need to be adjusted for older age as there is limited benefit from treating mild subclinical hypothyroidism

32.8 Risk factors for falls

- Muscle weakness
- History of falls
- Gait or balance abnormality
- Use of a walking aid
- Visual impairment
- Arthritis
- Impaired activities of daily living
- Depression
- Cognitive impairment
- Age over 80 years
- Psychotropic medication

32.9 Abnormal gaits and probable causes

Gait abnormality	Probable cause
Antalgic	Arthropathy
Waddling	Proximal myopathy
Stamping	Sensory neuropathy
Foot drop	Peripheral neuropathy or radiculopathy
Ataxic	Sensory neuropathy or cerebellar disease
Shuffling/festination	Parkinson disease
Marche à petits pas	Small-vessel cerebrovascular disease
Hemiplegic	Cerebral hemisphere lesion

i 32.10 Evidence-based interventions to reduce the risk of falls and fractures

- Exercise (should include components of lower limb strength and balance training):
  - Multimodal group exercise and Tai Chi are both effective
- Calcium and vitamin D supplementation:
  - Main evidence of effectiveness for patients in institutional care
- Home environment assessment and modification
- Medication review:
  - Particularly medications with central actions such as hypnotics but also those with anticholinergic and hypotensive actions
- Cataract surgery:
  - Effective if for first cataract
  - Other vision interventions ineffective and may increase falls risk
- Anti-slip shoes:
  - Effective only in icy conditions
- Cardiac pacemaker for carotid sinus hypersensitivity

delivered by physiotherapists or other suitably trained practitioners. An assessment of the patient's home environment for hazards should be undertaken by an occupational therapist, who may also provide personal alarms so that the person can summon help should they fall again. A medication review is required, rationalising medications that may be contributing to sedation, syncope or postural hypotension.

Calculation of fracture risk using tools such as FRAX or QFracture should be performed and dual X-ray absorptiometry (DXA) bone density scanning considered in patients with high risk of major osteoporotic fracture. If osteoporosis is diagnosed, specific drug therapy may be considered. In the frailest older adults, such as those in institutional care, calcium and vitamin D_3 supplements may reduce both falls and fractures.

Dizziness

Dizziness is very common, affecting at least 30% of those aged over 65 years in community surveys. It can be disabling in its own right and is also a risk factor for falls and functional decline.

The management of dizzy spells is complicated by the difficulty that patients have in describing the symptoms. Important questions in the history include establishing timing and whether it is an acute event (suggesting stroke) or a more chronic problem (such as a space-occupying lesion); whether continuous (for example, labyrinthitis) or episodic (for example, benign positional paroxysmal vertigo); and any provoking or relieving factors (for example, the effect of change in posture).

There may be a predominant symptom complex (although more than one of these may be present).

- *Pre-syncope, lightheadedness*, impending faint. Suggestive of reduced cerebral perfusion. While structural cardiac disease (aortic stenosis) and arrhythmia must be considered, autonomic disorders such as postural hypotension are the most common cause. Regardless of cause, antihypertensive medications may exacerbate symptoms and deprescribing may help.
- *Vertigo*, an illusion of movement. Suggestive of (peripheral) labyrinthine or (central) brainstem disease. In older patients this is most commonly due to peripheral causes, but if any brainstem symptoms or signs are present, MRI of the brain is required to exclude a central lesion.
- *Disequilibrium:* unsteadiness, off balance, veering to one side. Suggestive of joint or neurological disease.
- *Psychological:* anxiety and hyperventilation can be experienced as dizziness, or can complicate dizziness from other causes.

As with many conditions of older age, dizziness is often multifactorial. For example, a patient may have acute labyrinthitis in the context of small-vessel cerebrovascular disease and peripheral neuropathy. A multifaceted approach is needed and making small improvements in each contributing problem can have a large effect on symptoms and function.

Confusion (dementia and delirium)

Dementia

Dementia is a syndrome characterised by progressive loss of function across multiple cognitive domains (executive function, language, memory). The cognitive deficits should be sufficient to cause problems in everyday activities. Where a person has cognitive impairment but no functional limitation, this is often termed mild cognitive impairment. Further details on the assessment and management of dementia are available in Chapter 29. A common clinical problem is trying to establish whether an older adult presenting with confusion has pre-existing, and potentially undiagnosed cognitive decline, or a more acute change that may suggest delirium. To complicate the assessment, dementia and delirium commonly coexist. Cognitive screening of the patient can provide useful information and is described in Chapter 29. However, direct cognitive testing may not always be possible, particularly if the person is medically unwell. Collateral information from someone that knows the person well can be useful, and short structured interviews are available (Fig. 32.6).

Delirium

Delirium is a syndrome characterised by acute cognitive impairment, precipitated by an insult such as illness or surgery. Delirium is common, affecting around 25% of all hospital inpatients; 50% following hip fracture and 75% in intensive care. Delirium is associated with poor outcomes, including increased length of hospital stay, institutionalisation and mortality. Although traditionally considered a transient phenomenon, longer-lasting effects of delirium are described. In particular, delirium is a powerful risk factor for subsequent dementia and there is considerable overlap between 'persistent delirium' and dementia. The most important risk factors for delirium are frailty, dementia and a previous history of delirium. Other modifiable and non-modifiable risk factors are shown in Box 32.11.

Presentation

Delirium presents as an acute change (hours to days) in cognition that often fluctuates over time. Collateral information is crucial to assess whether impaired cognition in the context of illness represents an acute change (delirium) or is a more chronic phenomenon (more likely dementia). The defining neuropsychological feature of delirium is a deficit in attention, although this can be accompanied by problems in other cognitive domains. Based on psychomotor patterns, subtypes of delirium are described. Patients with hyperactive delirium are often agitated and restless, whereas hypoactive delirium can present as lethargy and sedation. A mixed picture with periods of hyper- and hypoactivity is common. Hypoactive delirium is more common in frailty and can be easily missed unless specifically looked for.

Assessment and management

In order to manage delirium effectively, the first step is to make a diagnosis. Screening tools such as the 4AT (Box 32.12) can be used to detect delirium and differentiate it from dementia, and these should be applied to all older patients admitted to hospital. Full physical assessment may be difficult, especially in hyperactive delirium if the person resists examination. Assessment for localising neurological signs and stigmata of head injury are essential as these would suggest the need for neuroimaging.

The best management of delirium is prevention. The landmark studies of the Hospital Elder Life Program demonstrated that a package of non-pharmacological interventions can reduce the incidence of delirium and its severity (see Box 32.11).

Once a diagnosis of delirium is established, the priority is to treat the underlying precipitating factors, recognising that these may be multiple. Life-threatening causes should be assessed for immediately, including sepsis, drug and alcohol intoxication or withdrawal, hypoglycaemia and other metabolic disorders. This should be followed by a systematic

Date: __________

AD8 Dementia Screening Interview

Remember, "Yes, a change" indicates that there has been a change in the last several years caused by cognitive (thinking and memory) problems	YES, A change	NO, No change	N/A, Don't know
1. Problems with judgement (e.g., problems making decisions, bad financial decisions, problems with thinking)			
2. Less interest in hobbies/activities			
3. Repeats the same thing over and over (questions, stories or statements)			
4. Trouble learning how to use a tool, appliance, or gadget (e.g., VCR, computer, microwave, remote control)			
5. Forgets correct month or year			
6. Trouble handling complicated financial affairs (e.g., balancing chequebook, income taxes, paying bills)			
7. Trouble remembering appointments			
8. Daily problems with thinking and/or memory			
TOTAL AD8 SCORE			

Fig. 32.6 Eight-item Informant Interview to Differentiate Ageing and Dementia (AD8). The AD8 is a screening test for the early cognitive changes that are common to many forms of dementia (Alzheimer disease, frontotemporal, vascular dementia). The test is best used as part of an interview with an informant, e.g. spouse, care-giver. A score of 2 or more 'Yes' answers suggests that a cognitive syndrome is likely. *From Galvin JE, et al. 32.11 Multicomponent interventions to prevent delirium

Risk factor	Intervention
Bowel and bladder	Assess and treat constipation, avoid urinary catheters
Dehydration	Regular assessment and prompting for fluids and food
Environmental	Orientation and cognitive stimulation activities; limit ward moves
Medications	Medication review and stopping or reducing culprit drugs
Sleep disturbance	Noise reduction (ear plugs), non-pharmacological sleeping aids
Sensory impairment	Screen for visual and hearing impairments, adaptive equipment (large-text, hearing aids)

approach to look for and treat any other potentially reversible precipitants, remembering that in frailty, seemingly trivial factors such as constipation or a urinary catheter may be sufficient to cause or prolong delirium. An accurate drug and alcohol history is required with a focus on any drugs recently started or stopped. Interventions that may promote recovery from delirium are similar to those that prevent delirium and include an environment that permits orientation (clocks, windows) and minimises external stimuli. Management also includes prevention of complications by attending to hydration, nutrition and early mobilisation. The role of drug therapy in delirium is controversial and most guidelines recommend non-pharmacological strategies as first line. However, in a patient with psychotic features who is extremely distressed, or where safety is at risk, a trial of low-dose antipsychotic medication may be indicated.

Continence

Both urinary and faecal incontinence are common in older age, but they are not an inevitable consequence of ageing. These conditions are under-diagnosed and often only come to medical attention when sufficiently severe to cause a social or hygiene problem. Many older adults may not volunteer problems with continence due to embarrassment or wrongly attributing the symptoms as a natural consequence of ageing. Sensitive enquiry into bladder and bowel health should be a routine part of the medical history. New incontinence can be a sign of acute illness and a sudden change in continence always demands thorough assessment.

Treatment should always begin with lifestyle changes and behavioural approaches (Fig. 32.7). Containment strategies, including catheters and pads, should never be viewed as first-line or definitive management, but may be required if the perineal skin is at risk of breakdown or quality of life is affected. True incontinence is not synonymous with 'functional' incontinence, where the problem is an inability to access a toilet in time rather than an issue with the mechanics of excretion.

Bladder health

Urinary incontinence is defined as the involuntary loss of urine. It occurs in all age groups but is especially common in older age and frailty, with up to 80% of care-home residents being incontinent of urine. The initial

32.12 How to make a diagnosis of delirium: the 4A Test (4AT)

1 Alertness

This includes patients who may be markedly drowsy (e.g. difficult to rouse and/or obviously sleepy during assessment) or agitated/hyperactive. Observe the patient. If asleep, attempt to wake with speech or gentle touch on shoulder. Ask the patient to state their name and address to assist rating:

Normal (fully alert and not agitated, throughout assessment)	0
Mild sleepiness for < 10 secs after waking, then normal	0
Clearly abnormal	4

2 Four-question abbreviated mental test (AMT4)

Ask the patient their age, date of birth, the place where they are (name of the hospital or building), the current year:

No mistakes	0
1 mistake	1
≥ 2 mistakes/untestable	2

3 Attention

Say to the patient: 'Please tell me the months of the year in backwards order, starting at December.' To assist initial understanding, one prompt of 'What is the month before December?' is permitted:

Achieves ≥ 7 months correctly	0
Starts but scores < 7 months/refuses to start	1
Untestable (cannot start because unwell, drowsy, inattentive)	2

4 Acute change or fluctuating course

Evidence of significant change or fluctuation in: alertness, cognition, other mental function (e.g. paranoia, hallucinations) arising over the last 2 weeks and still evident in last 24 hrs:

No	0
Yes	4

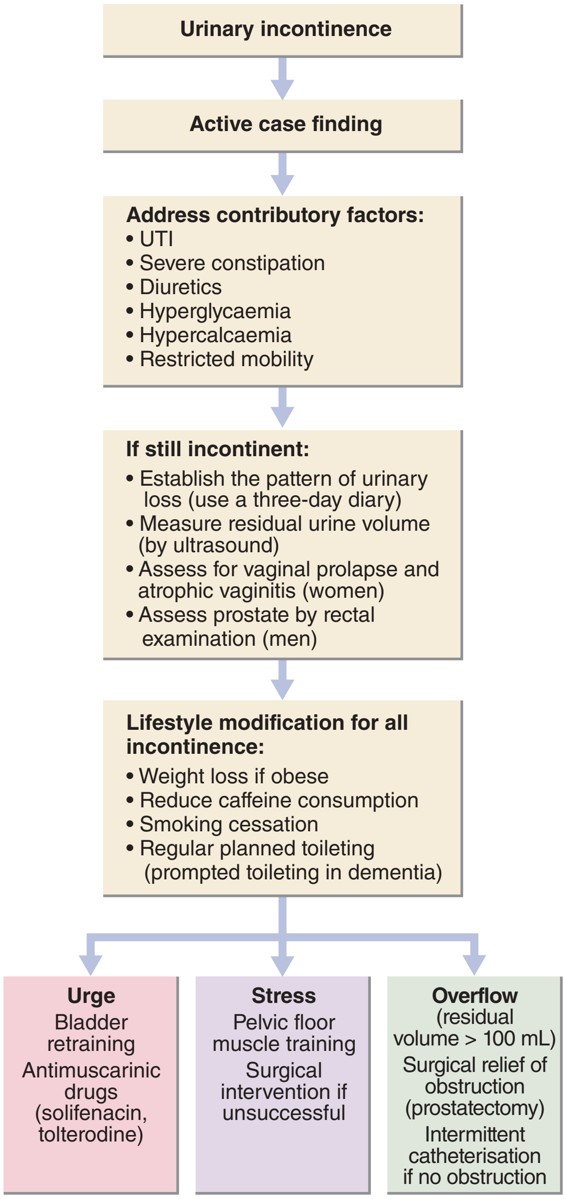
Total 4AT score (maximum possible score 12)

- **≥ 4**: possible delirium ± cognitive impairment
- **1–3**: possible cognitive impairment
- **0**: delirium or severe cognitive impairment unlikely (but delirium still possible if information in 4 incomplete)

assessment should seek to identify and address contributory factors, and some of these may be easily remedied, for example infection, constipation and pelvic prolapse. Interventions including weight loss, reducing caffeine and regular planned toileting can be useful regardless of the aetiology of incontinence.

Clinical assessment should establish the pattern of urinary loss (a bladder diary may be used), examine the pelvic organs (prolapse and atrophic vaginitis or prostatic enlargement) and assess for residual urine volume by ultrasound. The type of incontinence should be ascertained, as this will guide subsequent treatment.

- *Urgency incontinence* is usually due to detrusor over-activity and results in urgency and frequency. Bladder retraining is the first-line intervention; occasionally antimuscarinic medications are needed but these should be used with caution in frailty and cognitive impairment.
- *Stress incontinence* is due to weakness of the pelvic floor muscles, which allows leakage of urine when intra-abdominal pressure rises, such as on coughing. It may be compounded by atrophic vaginitis, associated with oestrogen deficiency in old age, which can be treated with oestrogen pessaries. Pelvic floor muscle training is first-line treatment, but surgery can be needed.
- *Overflow incontinence* is demonstrated by a significant post-void residual on bladder scanning. It is most commonly seen in older men with prostatic enlargement, which obstructs bladder outflow.



Urinary incontinence
Active case finding
Address contributory factors:
• UTI
• Severe constipation
• Diuretics
• Hyperglycaemia
• Hypercalcaemia
• Restricted mobility
If still incontinent:
• Establish the pattern of urinary loss (use a three-day diary)
• Measure residual urine volume (by ultrasound)
• Assess for vaginal prolapse and atrophic vaginitis (women)
• Assess prostate by rectal examination (men)
Lifestyle modification for all incontinence:
• Weight loss if obese
• Reduce caffeine consumption
• Smoking cessation
• Regular planned toileting (prompted toileting in dementia)
Urge
Bladder retraining
Antimuscarinic drugs (solifenacin, tolterodine)
Stress
Pelvic floor muscle training
Surgical intervention if unsuccessful
Overflow
(residual volume > 100 mL)
Surgical relief of obstruction (prostatectomy)
Intermittent catheterisation if no obstruction

Fig. 32.7 **Assessment and management of urinary incontinence in old age.** See also Box 18.52. (UTI = urinary tract infection). *Based on European Association of Urology Guidelines 2018.*

- *Mixed incontinence* is demonstrated when more than one continence issue may be present, most commonly urgency and stress in females and overflow and urgency in males.

Bowel health

Problems with bowel habit are often multifactorial and may result from cognitive factors, local bowel factors and external factors such as immobility. Assessment should include enquiring about diet, medication, previous surgery and lifelong bowel habit. The examination should include an anorectal assessment looking for prolapse, anal tone and faecal loading.

In patients with severe stroke disease or dementia, treatment may be difficult as cortical inhibitory signals are lost. A timed/prompted toileting programme may help.

Infection in the older adult

Infection is one of the commonest reasons for older adults to seek medical attention. All the considerations around disease in older age and frailty that have been discussed in this chapter remain pertinent in relation to infection – non-specific presentations, challenges of comorbidity, competing risks and benefits of interventions. In fact, infection could be considered an exemplar of the need for an adapted management strategy in older age.

Ageing and the immune system

Older adults, particularly those living with frailty, face an increased risk and severity of infection. Although absolute numbers of immune cells do not change substantially with age, immune function decreases leading to less efficient responses of both innate and adaptive immune systems, sometimes referred to as immunosenescence. Age-related changes in anatomy and physiology also predispose to infection. For example, blunting of cough reflex, impaired mucociliary clearance and decreased respiratory muscle strength with subsequent hypoventilation increase the risk of pulmonary infection. Age-related changes in bladder function and thinning of the skin may partly explain the high prevalence of urinary infection with older age. Factors that are common in older adults but not part of biological ageing are also important. These include multiple morbidity, polypharmacy (including use of antibiotics and immunosuppressants) and environmental exposures to pathogens.

Assessment

The diagnosis of infection in older age is challenging as symptoms and signs are often atypical and non-specific. Frailty syndromes of delirium and functional decline are common, while ‘classical’ features of the disease may be absent. Older adults have a lower baseline temperature and blunted or absent fever response to infection. Thus, a core temperature of greater than 38°C is likely to be indicative of important disease. Unfortunately, the temperature response is non-specific in older adults and non-infective causes such as myocardial infarction and deep vein thrombosis need to be considered. The commonest infection sites in older age are respiratory, urinary and skin. However, with frailty, atypical infections and infections in atypical sites are often seen. Thus, the assessment of the unwell older adult always needs to consider infection, and physical examination needs to be comprehensive including pressure areas, oral cavity and intravenous cannulation sites. Consideration of the patient’s environment may offer clues to the underlying pathogen. The patient from a care home or who has had a prolonged hospital admission will be at risk from differing causative pathogens to the robust community-dwelling older adult.

Management

Treating infection in older adults poses further challenges. The pharmacokinetics and pharmacodynamics of antibiotics change with ageing and older adults are at greater risk of adverse drug reactions. Given the difficulty of making an initial diagnosis, the use of empirical broad-spectrum antibiotics may seem intuitive, but this approach is strongly discouraged not least due to the risks of *Clostridioides difficile* infection and promoting antibiotic-resistant strains. If the patient is not septic or rapidly deteriorating, there should be time for investigations, including relevant cultures, before initiating antibiotic therapy. In liaison with the microbiology laboratory, the prescribed therapy can be rationalised as results become available.

Health-care associated infection is a particular concern in frailty, and all staff working with older adults need to be mindful of infection control policies including meticulous hand washing between patient encounters. Without these measures, hospital ward and institutional care settings are at risk of outbreaks of diseases such as norovirus, scabies, methicillin-resistant *Staphylococcus aureus* and, more recently, COVID-19.

Prescribing and deprescribing

The multimorbidity that accompanies ageing often leads to polypharmacy (Box 32.13 and see Box 2.24). This has been defined as the use of four or more drugs, and is associated with adverse outcomes including falls, hospitalisation and increased risk of death. While some of these outcomes are caused by drug–drug interactions and adverse effects, others are due to the underlying problems for which the drugs were prescribed in the first place.

i 32.13 Factors leading to polypharmacy in old age

- Multiple pathology
- Poor patient education
- Lack of routine review of all medications
- Patient expectations of prescribing
- Over-use of drug interventions by doctors
- Attendance at multiple specialist clinics
- Poor communication between specialists

i 32.14 Common adverse drug reactions in old age

Drug class	Adverse reaction
NSAIDs	Gastrointestinal bleeding Renal impairment
Diuretics	Renal impairment, electrolyte disturbance Hypotension, postural hypotension
Warfarin **Anticoagulants**	Bleeding (any site)
ACE inhibitors	Renal impairment Hypotension, postural hypotension
Beta-adrenoceptor antagonists (β-blockers)	Bradycardia, heart block Hypotension, postural hypotension
Opiates	Vomiting Urinary retention, constipation
Antidepressants	Hyponatraemia (SSRIs) Hypotension, postural hypotension
Benzodiazepines	Delirium Falls
Anticholinergics	Delirium Urinary retention, constipation

(ACE = angiotensin-converting enzyme; NSAIDs = non-steroidal anti-inflammatory drugs; SSRIs = selective serotonin re-uptake inhibitors)

An important component of any older adult assessment is a critical review of medications. This group can be the victim of well-intentioned, but ultimately harmful, prescribing cascades where new medications are introduced to combat effects of other medications and these new medications in turn have adverse effects that result in further prescribing. Of course, for many older people, taking multiple drugs is entirely appropriate, as such therapy is required to treat multiple diseases. Getting the right balance between over- and under-treatment is a dynamic process and requires frequent, careful exploration of the person’s treatment goals.

Adverse drug reactions

The more drugs that are taken, the greater the risk of an adverse drug reaction (ADR) (Box 32.14). ADRs are the cause of around 5% of all hospital admissions but account for up to 20% of admissions in those aged over 65 years. Older people are especially sensitive to drugs that can cause postural hypotension or volume depletion, and centrally acting drugs can often cause or exacerbate cognitive syndromes. However, the clinical presentations of ADRs are diverse, so for any presenting problem in old age, the possibility that the patient’s medication is a contributory factor should always be considered. Prescribers must also be mindful of the burden of taking medications at various times, with need for monitoring, lifestyle restrictions and associated expense. It is perhaps not surprising that non-adherence to drug therapy rises with the number of drugs prescribed.

Appropriate prescribing and deprescribing

The key to appropriate prescribing is first to ensure that medications are started only for reasons that accord with the patient's goals and wishes. Thoughtless adherence to specialist guidelines quickly leads to polypharmacy that may be inappropriate. Some medications (such as chronic use of non-steroidal anti-inflammatory medications) are best avoided in older people because of the high risk of ADR. Other medications, such as oral bisphosphonates, lack evidence of efficacy in very old people, who may not live for long enough to derive benefit.

Deprescribing is as important as prescribing in older people. Regular review of medications should be undertaken to ensure that medications are still required, to establish that they are still working, to check that they are not causing side-effects and to ascertain whether the patient is actually taking them. The patient or care-giver should be asked to bring all medication for review rather than the doctor relying on previous records. Such reviews should take place regularly, not just at a point of crisis such as after a fall or on hospital admission. Deprescribing of medications that have been taken for years needs to be done in a controlled manner, with dose reduction to ensure that rebound symptoms or withdrawal effects do not occur.

There are tools to assist with rational prescribing choices in older adults. The American Geriatrics Society Beers Criteria is an expert-generated list of medications that should be avoided or used with caution in old age. A similar European initiative is STOPP (Screening Tool of Older Person's Prescriptions) and START (Screening Tool to Alert to Right Treatment), which recognises that good prescribing in old age should ensure effective treatments are prioritised as well as discontinuing those medications that may be of limited benefit or potential harm.

Other problems in old age

A range of other presenting problems in older people present to many medical specialties. End-of-life care is an important facet of clinical practice in old age and the general principles of this are discussed in Chapter 9. Relevant sections in other chapters are shown in Box 32.15.

Within each chapter, 'In Old Age' boxes highlight the areas in which presentation or management differs from that in younger individuals.

Multiple Choice Questions

32.1. An 85-year-old retired professor attends the clinic. His family describe 2 years of worsening memory. He repeats stories, is no longer able to pay bills and becomes lost when going to the shops. On examination he is alert and chatty, with no localising neurology. You perform a Montreal Cognitive Assessment and he scores 27/30 (normal range 26–30). What is the most likely diagnosis?

A. Mild cognitive impairment
B. Dementia
C. Delirium
D. Depressive pseudo-dementia
E. Subdural haematoma

Answer: B.

There is a clear description of progressive cognitive decline causing functional problems; these are the main features of dementia. His 'normal' cognitive score does not alter the likely diagnosis; the test used is a screening test and false negatives are often seen in highly educated people. Mild cognitive impairment implies cognitive change with no functional consequence. The presentation and symptom duration would not be in keeping with delirium or pseudo-dementia. Subdural haematoma is unlikely with no neurological signs.

32.2. A 98-year-old woman is admitted to hospital with pneumonia that presents as delirium, falls and new incontinence in the context of complex morbidity and polypharmacy. Which of these models of care is likely to give the best outcomes?

A. Admission to dedicated geriatric medicine ward with multidisciplinary team
B. Admission to critical care ward with multidisciplinary team
C. Admission to respiratory ward with consult from geriatric medicine
D. Discharge home with outpatient follow-up
E. Discharge to care home

Answer: A.

This woman has evidence of frailty and will benefit from Comprehensive Geriatric Assessment (CGA). Evidence suggests that CGA works best when delivered in a dedicated space with a multidisciplinary team. Other models of CGA such as peripatetic or outpatient clinic consultations are less effective. It is unlikely she would tolerate or benefit from organ support and so critical care is not appropriate. She is too unwell to immediately discharge home.

32.3. A 99-year-old woman presents with an acute coronary syndrome in the context of frailty. She makes a good recovery and echocardiogram suggests preserved left ventricular function, but she continues to experience angina symptoms on exertion. Random blood glucose is high (11.0 mmol/L, 198 mg/dL) and blood pressure is 172/88 mmHg. She wishes to avoid taking tablets. Which of these medications would you want to prioritise?

A. Insulin
B. Angiotensin-converting enzyme (ACE) inhibitor
C. Statin
D. Alpha-adrenoceptor antagonist (α-blocker)
E. Amlodipine

Answer: E.

In an older adult with frailty, prescribing decisions may not always follow guideline recommendations for younger patients. A statin and ACE inhibitor have prognostic benefits that may not be realised in this patient. She wants to limit her medication burden, and amlodipine offers anti-anginal and antihypertensive effects. Alpha-blockers offer only antihypertensive action and are poorly tolerated in older adults. A diagnosis of diabetes mellitus has not been made and so there is no role for insulin.

32.4. An 88-year-old man slips on ice and fractures his distal right radius. He is right-hand dominant. He is usually mobile with a stick. He requires joint immobilisation and is admitted for a period of geriatric assessment. On assessment of activity of daily living, he struggles to dress due to his fracture. The occupational therapist gives him a tool to assist with buttons and zips. At which level of the World Health Organization International Classification of Functioning, Disability and Health (WHO ICF) is this intervention directed?

A. Activity
B. Disability
C. Handicap
D. Impairment
E. Quality of life

Answer: A.

In the WHO ICF, Activity (A) describes the execution of a task or action by an individual. The term disability (B) is now taken as a general term for impairments, activity limitations and participation restrictions. The term handicap (C) is no longer used and has been replaced by societal participation. Impairment (D) refers to problems in body structure and function. Quality of life is not part of the WHO ICF.

32.5. A usually well 84-year-old man presents with new-onset urinary incontinence. He has little past medical history but has been taking non-steroidal anti-inflammatories for worsening back pains over the last weeks. On initial physiotherapy assessment he is found to have difficulty walking. What is the most appropriate management of his incontinence?

A. Further physiotherapy to improve back pain and mobility
B. Pelvic floor muscle training
C. Prescription of α-blockers for presumed prostatic hypertrophy
D. MRI scanning of spinal cord
E. Empirical antibiotics pending urine culture

Answer: D.

New-onset incontinence should not be accepted as a natural consequence of ageing. In this case the back pain and change in mobility are suggestive of potential spinal cord compression and demand immediate imaging. Physiotherapy, screening for urinary tract infection and assessing for prostatic hypertrophy could all be useful once spinal cord compression is excluded. Pelvic floor training has greatest benefit in women with stress incontinence.

32.6. An 87-year-old man presents with recent falls. He describes three injurious falls in the last day, one of which was associated with facial injury. All the falls are associated with walking. He does not remember falling and thinks he may have ‘blacked out’. His wife states that he makes an immediate recovery after the falls. Examination is normal, blood pressure is 136/82 mmHg supine, 130/78 standing at 2 minutes. Which investigation is needed first?

A. CT brain scan
B. Random cortisol
C. Timed get up and go test
D. Twelve-lead ECG
E. Ambulatory blood pressure monitor

Answer: D.

New-onset, recurrent falls with injury and loss of consciousness is highly suggestive of cardiac syncope. Although there is facial injury, the lack of localising neurology and no epileptiform features make an intracranial lesion or injury unlikely. He has a modest drop in blood pressure on standing that is not sufficient to explain the presentation. A timed get up and go test can identify people requiring multidisciplinary falls input, but in this case the falls seem related to syncope rather than disordered gait and balance.

Laboratory reference ranges

Notes on the international system of units (SI units) 1352
Laboratory reference ranges in adults 1352
- Urea and electrolyte analytes in venous blood 1352
- Analytes in arterial blood 1352
- Hormones in venous blood 1353
- Other common analytes in venous blood 1354
- Common analytes in urine 1355
- Analytes in cerebrospinal fluid (CSF) 1355
- Analytes in faeces 1355
- Haematological analytes 1356
- Immunological analytes in venous blood 1357

Laboratory reference ranges in childhood and adolescence 1358
- Analytes that may be significantly affected by growth and puberty 1358

Laboratory reference ranges in pregnancy 1359
- Analytes that may be significantly affected by pregnancy 1359

Notes on the international system of units (SI units)

Système International (SI) units are a specific subset of the metre–kilogram–second system of units and were agreed on as the everyday currency for commercial and scientific work in 1960, following a series of international conferences organised by the International Bureau of Weights and Measures. SI units have been adopted widely in clinical laboratories, but non-SI units are still used in many countries. For that reason, values in both units are given for common measurements throughout this textbook and commonly used non-SI units are shown in this chapter. The SI unit system is, however, recommended.

Examples of basic SI units

Length	metre (m)
Mass	kilogram (kg)
Amount of substance	mole (mol)
Energy	joule (J)
Pressure	pascal (Pa)
Volume	The basic SI unit of volume is the cubic metre (1000 litres). For convenience, however, the litre (L) is used as the unit of volume in laboratory work.

Examples of decimal multiples and submultiples of SI units

Factor	Name	Prefix
10^{6}	mega-	M
10^{3}	kilo-	k
10^{-1}	deci-	d
10^{-2}	centi-	c
10^{-3}	milli-	m
10^{-6}	micro-	μ
10^{-9}	nano-	n
10^{-12}	pico-	p
10^{-15}	femto-	f

Exceptions to the use of SI units

By convention, blood pressure is excluded from the SI unit system and is measured in mmHg (millimetres of mercury) rather than pascals.

Mass concentrations such as g/L and μg/L are used in preference to molar concentrations for all protein measurements and for substances that do not have a sufficiently well-defined composition.

Some enzymes and hormones are measured by ‘bioassay’, in which the activity in the sample is compared with the activity (rather than the mass) of a standard sample that is provided from a central source. For these assays, results are given in standardised ‘units’ (U/L), or ‘international units’ (IU/L), which depend on the activity in the standard sample and may not be readily converted to mass units.

Laboratory reference ranges in adults

Reference ranges are largely those used in the Departments of Clinical Biochemistry and Haematology, NHS Lothian, Edinburgh, UK. Values are shown in both SI units and, where appropriate, non-SI units. Many reference ranges vary between laboratories, depending on the assay method used and on other factors; this is especially the case for enzyme assays. Wherever possible an internationally agreed standard reference material is used to calibrate assays, and reference ranges and assay nomenclature are standardised between laboratories. The origin of reference ranges and the interpretation of ‘abnormal’ results are discussed on page 3. No details are given here of the collection requirements, which may be critical to obtaining a meaningful result. Unless otherwise stated, reference ranges shown apply to adults; values in children may be different.

Many analytes can be measured in either serum (the supernatant of clotted blood) or plasma (the supernatant of anticoagulated blood). A specific requirement for one or the other may depend on a kit manufacturer’s recommendations. In other instances, the distinction is critical. An example is fibrinogen, where plasma is required, since fibrinogen is largely absent from serum. In contrast, serum is required for electrophoresis to detect paraproteins because fibrinogen migrates as a discrete band in the zone of interest.

33.1 Urea and electrolyte analytes in venous blood

	Reference range	
Analysis	**SI units**	**Non-SI units**
Sodium	135–145 mmol/L	135–145 mEq/L
Potassium*	3.6–5.0 mmol/L	3.6–5.0 mEq/L
Chloride	95–107 mmol/L	95–107 mEq/L
Urea	2.5–6.6 mmol/L	15–40 mg/dL
Creatinine		
Male	64–111 μmol/L	0.72–1.26 mg/dL
Female	50–98 μmol/L	0.57–1.11 mg/dL

*Serum values are, on average, 0.3 mmol/L higher than plasma values.

33.2 Analytes in arterial blood

	Reference range	
Analysis	**SI units**	**Non-SI units**
Bicarbonate	21–29 mmol/L	21–29 mEq/L
Hydrogen ion	37–45 nmol/L	pH 7.35–7.43
$Pa\text{CO}_2$	4.5–6.0 kPa	34–45 mmHg
$Pa\text{O}_2$	12–15 kPa	90–113 mmHg
Oxygen saturation	> 97%	

33.3 Hormones in venous blood

	Reference range	
Hormone	**SI units**	**Non-SI units**
Adrenocorticotrophic hormone (ACTH) (plasma)	1.5–13.9 pmol/L (0700–1000 hrs)	63 ng/L
Aldosterone		
Supine (at least 30 mins)	30–440 pmol/L	1.09–15.9 ng/dL
Erect (at least 1 hr)	110–860 pmol/L	3.97–31.0 ng/dL
Chromogranin A	< 60 pmol/L	< 102 µg/L
Copeptin	≤ 4.9 pmol/L during osmotic stimulation indicates AVP deficiency	≤ 19.7 pg/mL
	> 21.4 pmol/L indicates complete or partial AVP resistance	> 85.9 pg/mL
Cortisol	Dynamic tests are required – see Box 20.51	
C-peptide	0.17–0.90 nmol/L	0.51–2.72 ng/mL
	C-peptide levels reflect output of insulin from pancreatic β cells and should be interpreted in relation to the clinical situation	
Fibroblast growth factor 23 (FGF23)	< 100 RU/mL	–
Follicle-stimulating hormone (FSH)		
Male	1.0–10.0 IU/L	–
Female	3.0–10.0 IU/L (early follicular)	–
	> 30 IU/L (post-menopausal)	–
Gastrin (plasma, fasting)	< 40 pmol/L	< 83 pg/mL
Growth hormone (GH)	Dynamic tests are usually required	
	< 0.5 µg/L excludes acromegaly (if insulin-like growth factor 1 (IGF-1) in reference range) – see page 739	< 2 mIU/L
	> 6.7 µg/L excludes GH deficiency –see Box 20.54	> 18 mIU/L
Insulin	Highly variable and interpretable only in relation to plasma glucose and body habitus	
Luteinising hormone (LH)		
Male	1.0–9.0 IU/L	–
Female	2.0–9.0 IU/L (early follicular)	–
	> 20 IU/L (post-menopausal)	–
Metadrenalines (plasma)		
Metadrenaline	< 510 pmol/L	< 100 ng/L
Normetadrenaline	< 1180 pmol/L	< 216 ng/L
3-methoxytyramine	< 180 pmol/L	< 30 ng/L
17β-Oestradiol		
Male	< 160 pmol/L	< 43 pg/mL
Female	75–140 pmol/L (early follicular)	20–38 pg/mL
	< 150 pmol/L (post-menopausal)	< 41 pg/mL
Parathyroid hormone (PTH)	1.6–6.9 pmol/L	16–69 pg/mL
Progesterone (in luteal phase in women)		
Consistent with ovulation	> 30 nmol/L	> 9.3 ng/mL
Probable ovulatory cycle	15–30 nmol/L	4.7–9.3 ng/mL
Anovulatory cycle	< 10 nmol/L	< 3 ng/mL
Prolactin (PRL)	60–500 mIU/L	2.8–23.5 ng/mL
Renin concentration		
Supine (at least 30 mins)	5–40 mIU/L	–
Sitting (at least 15 mins)	5–45 mIU/L	–
Erect (at least 1 hr)	16–63 mIU/L	–
Testosterone		
Male	10–38 nmol/L	290–1090 ng/dL
Female	0.3–1.9 nmol/L	10–90 ng/dL
Thyroid-stimulating hormone (TSH)	0.2–4.5 mIU/L	–
Thyroxine (free), (free T4)	9–21 pmol/L	0.7–1.63 ng/dL
Triiodothyronine (free), (free T3)	2.6–6.2 pmol/L	0.16–0.4 ng/dL
Vitamin D (25(OH)D)		
Normal	> 50 nmol/L	> 20 ng/mL
Insufficiency	25–50 nmol/L	10–20 ng/mL
Deficiency	< 25 nmol/L	< 10 ng/mL

Notes

1. A number of hormones are unstable and collection details are critical to obtaining a meaningful result. Refer to local laboratory handbook.
2. Values in the table are only a guideline; hormone levels can often be meaningfully understood only in relation to factors such as gender, age, time of day, pubertal status, stage of the menstrual cycle, pregnancy and menopausal status.
3. Vitamin D levels vary seasonally in many parts of the world, with levels being higher in the summer months in most people due to increased exposure to solar UVB rays.
4. Reference ranges are usually dependent on the method used for analysis and frequently differ between laboratories. Non-SI units also differ; those shown here are amongst those most widely used. Readers are encouraged to consult their local laboratory for non-SI units for individual analytes and their respective reference ranges.

(RU = relative units. Relative units are used since at the present time there is no agreed international standard for the measurement of FGF23.)

33.4 Other common analytes in venous blood

	Reference range	
Analyte	**SI units**	**Non-SI units**
α1-Antitrypsin	1.1–2.1 g/L	110–210 mg/dL
Alanine aminotransferase (ALT)	10–50 U/L	–
Albumin	35–50 g/L	3.5–5.0 g/dL
Alkaline phosphatase (ALP)	40–125 U/L	–
Amylase	< 100 U/L	–
Aspartate aminotransferase (AST)	10–45 U/L	–
Bile acids (fasting)	< 14 μmol/L	–
Bilirubin (total)	3–21 μmol/L	0.18–1.23 mg/dL
Caeruloplasmin	0.2–0.47 g/L	20–47 mg/dL
Calcium (total)	2.2–2.6 mmol/L	4.2–5.2 mEq/L or 8.5–10.5 mg/dL
Carboxyhaemoglobin	0.1%–3.0% Levels of up to 8% may be found in heavy smokers	–
Cholesterol (total)	Ideal level varies according to cardiovascular risk (see p. 681)	
High-density lipoprotein (HDL)-cholesterol	Ideal level varies according to cardiovascular risk, so reference ranges can be misleading. According to the National Cholesterol Education Programme Adult Treatment Panel III (ATPIII), a low HDL-cholesterol is < 1.0 mmol/L (< 40 mg/dL)	
Complement		
C3	0.81–1.57 g/L	–
C4	0.13–1.39 g/L	–
Total haemolytic complement	0.086–0.410 g/L	–
Copper	10–22 μmol/L	64–140 μg/dL
C-reactive protein (CRP)	< 5 mg/L Highly sensitive CRP assays also exist that measure lower values and may be useful in estimating cardiovascular risk	
Creatine kinase (CK; total)*		
Male	40–320 U/L	–
Female	25–200 U/L	–
Creatine kinase MB isoenzyme	< 6% of total CK	–
Ethanol	Not normally detectable	
Marked intoxication	65–87 mmol/L	300–400 mg/dL
Stupor	87–109 mmol/L	400–500 mg/dL
Coma	> 109 mmol/L	> 500 mg/dL
γ-Glutamyl transferase (GGT)	Male 10–55 U/L Female 5–35 U/L	–
Glucose (fasting)	3.6–5.4 mmol/L See Box 21.2 for definitions of impaired glucose tolerance, impaired fasting glycaemia and diabetes mellitus, and Box 21.14 for definition of hypoglycaemia	65–97 mg/dL
Glycated haemoglobin (HbA1c)	4.0%–6.0% 20–41 mmol/mol Hb See Box 21.2 for diagnosis of diabetes mellitus and pre-diabetes	–
Immunoglobulins (Ig)		
IgA	0.8–4.5 g/L	–
IgE	0–250 kU/L	–
IgG	6.0–15.0 g/L	–
IgM	0.35–2.90 g/L	–
Lactate	0.6–2.4 mmol/L	5.4–21.6 mg/dL
Lactate dehydrogenase (LDH; total)	125–220 U/L	–
Lead	< 0.5 μmol/L	< 10 μg/dL
Magnesium	0.75–1.0 mmol/L	1.5–2.0 mEq/Lor 1.82–2.43 mg/dL
Osmolality	280–296 mOsmol/kg	–
Osmolarity	280–296 mOsmol/L	–
Phosphate (fasting)	0.8–1.4 mmol/L	2.48–4.34 mg/dL
Procalcitonin	< 0.1 μg/L (indicates absence of bacterial infection) < 0.24 μg/L (bacterial infection unlikely) 0.25–0.49 μg/L (bacterial infection is possible) ≥0.5 μg/L (suggestive of the presence of bacterial infection)	–
Protein (total)	60–80 g/L	6–8 g/dL
Triglycerides (fasting)	0.6–1.7 mmol/L	53–150 mg/dL
Troponins	Values consistent with myocardial infarction are crucially dependent on which troponin is measured (I or T) and on the method employed. Interpret in context of clinical presentation. See Box 16.47	
Tryptase	0–135 mg/L	–
Urate		
Male	120–420 μmol/L	2.0–7.0 mg/dL
Female	120–360 μmol/L	2.0–6.0 mg/dL
Zinc	10–18 μmol/L	65–118 μg/dL

*CK levels vary according to ethnicity, such that people of African and Caribbean origin typically have CK levels 1.5 to 2 times higher than people of European descent.

33.5 Common analytes in urine

	Reference range	
Analyte	**SI units**	**Non-SI units**
Albumin	Definitions of albuminuria are given in Box 18.11	
Calcium (normal diet)	Up to 7.5 mmol/24 hrs	Up to 15 mEq/24 hrs or 300 mg/24 hrs
Copper	< 0.6 µmol/24 hrs	< 38 µg/24 hrs
Cortisol	31–282 nmol/24 hrs	11–102 µg/24 hrs
Creatinine		
Male	6.3–23 mmol/24 hrs	712–2600 mg/24 hrs
Female	4.1–15 mmol/24 hrs	463–1695 mg/24 hrs
5-Hydroxyindole-3-acetic acid (5-HIAA)	10–42 µmol/24 hrs	1.9–8.1 mg/24 hrs
Metadrenalines		
Normetadrenaline	0.4–3.4 µmol/24 hrs	73–620 µg/24 hrs
Metadrenaline	0.3–1.7 µmol/24 hrs	59–335 µg/24 hrs
Oxalate	0.04–0.49 mmol/24 hrs	3.6–44 mg/24 hrs
Phosphate	15–50 mmol/24 hrs	465–1548 mg/24 hrs
Potassium*	25–100 mmol/24 hrs	25–100 mEq/24 hrs
Protein	Definitions of proteinuria are given in Box 18.11	Definitions of proteinuria are given in Box 18.11
Sodium*	100–200 mmol/24 hrs	100–200 mEq/24 hrs
Urate	1.2–3.0 mmol/24 hrs	202–504 mg/24 hrs
Urea	170–600 mmol/24 hrs	10.2–36.0 g/24 hrs
Zinc	3–21 µmol/24 hrs	195–1365 µg/24 hrs

*The urinary output of electrolytes such as sodium and potassium is normally a reflection of dietary intake. This can vary widely. The values quoted are appropriate to a 'Western' diet.

33.6 Analytes in cerebrospinal fluid (CSF)

	Reference range	
Analysis	**SI units**	**Non-SI units**
Cells	$< 5 \times 10^6$ cells/L (all mononuclear)	< 5 cells/mm^3
Glucose[1]	2.3–4.5 mmol/L	41–81 mg/dL
IgG index[2]	< 0.65	–
Total protein	0.14–0.45 g/L	0.014–0.045 g/dL

[1] Interpret in relation to plasma glucose. Values in CSF are typically approximately two-thirds of plasma levels.

[2] A crude index of increase in IgG attributable to intrathecal synthesis.

(IgG = immunoglobulin G)

33.7 Analytes in faeces

	Reference range	
Analyte	**SI units**	**Non-SI units**
Calprotectin	< 50 µg/g	–
Elastase	> 200 µg/g	–
Haemoglobin	< 10 µg/g	–

33.8 Haematological analytes

	Reference range	
Analysis	**SI units**	**Non-SI units**
Bleeding time (Ivy method)	< 8 mins	–
Blood volume		
Male	65–85 mL/kg	–
Female	60–80 mL/kg	–
Coagulation screen		
Prothrombin time (PT)	10.5–13.5 secs	–
Activated partial thromboplastin time (APTT)	26–36 secs	–
D-dimers		
Interpret in relation to clinical presentation	< 500 ng/mL	–
Erythrocyte sedimentation rate (ESR)	Higher values in older patients are not necessarily abnormal	
Adult male	0–10 mm/hr	–
Adult female	3–15 mm/hr	–
Ferritin		
Male (and post-menopausal female)	20–300 µg/L	20–300 ng/mL
Female (pre-menopausal)	15–200 µg/L	15–200 ng/mL
Fibrinogen	1.5–4.0 g/L	0.15–0.4 g/dL
Folate		
Serum	2.8–20 µg/L	2.8–20 ng/mL
Red cell	120–500 µg/L	120–500 ng/mL
Haemoglobin		
Male	130–180 g/L	13–18 g/dL
Female	115–165 g/L	11.5–16.5 g/dL
Haptoglobin	0.4–2.4 g/L	0.04–0.24 g/dL
Iron		
Male	14–32 µmol/L	78–178 µg/dL
Female	10–28 µmol/L	56–157 µg/dL
Leucocytes (adults)	4.0–11.0 × 10^9/L	4.0–11.0 × 10^3/mm^3
Differential white cell count		
Neutrophil granulocytes	2.0–7.5 × 10^9/L	2.0–7.5 × 10^3/mm^3
Lymphocytes	1.5–4.0 × 10^9/L	1.5–4.0 × 10^3/mm^3
Monocytes	0.2–0.8 × 10^9/L	0.2–0.8 × 10^3/mm^3
Eosinophil granulocytes	0.04–0.4 × 10^9/L	0.04–0.4 × 10^3/mm^3
Basophil granulocytes	0.01–0.1 × 10^9/L	0.01–0.1 × 10^3/mm^3
Mean cell haemoglobin (MCH)	27–32 pg	–
Mean cell volume (MCV)	78–98 fL	–
Packed cell volume (PCV) or haematocrit		
Male	0.40–0.54	–
Female	0.37–0.47	–
Platelets	150–350 × 10^9/L	150–350 × 10^3/mm^3
Red cell count		
Male	4.5–6.5 × 10^{12}/L	4.5–6.5 × 10^6/mm^3
Female	3.8–5.8 × 10^{12}/L	3.8–5.8 × 10^6/mm^3
Red cell lifespan		
Mean	120 days	–
Half-life (^{51}Cr)	25–35 days	–
Reticulocytes (adults)	25–85 × 10^9/L	25–85 × 10^3/mm^3
Transferrin	2.0–4.0 g/L	0.2–0.4 g/dL
Transferrin saturation		
Male	25%–50%	–
Female	14%–50%	–
Vitamin B_{12}		
Normal	> 210 ng/L	–
Intermediate	180–200 ng/L	–
Low	< 180 ng/L	–

33.9 Immunological analytes in venous blood

Autoantibody	Methodology	Results
Antimitochondrial antibodies	Indirect immunofluorescence	Results are reported as negative or positive on a 1 in 40 dilution of serum applied to target cells[1]
Antimitochondrial (M2) antibodies	ELISA	M2 negative: < 4 IU/mL M2 normal range: 4–6 IU/mL M2 positive: > 6 IU/mL
Anti-gastric parietal cell antibodies	Indirect immunofluorescence	Results are reported as negative or positive on a 1 in 40 dilution of serum applied to target cells[1]
Antineutrophil cytoplasmic antibodies (ANCA)	Indirect immunofluorescence	Results are reported as negative or positive on a 1 in 20 dilution of serum applied to target cells[2] Borderline (+/−), positive (+) and strongly positive (++) In addition, the following ANCA patterns are reported: pANCA, cANCA, and atypical ANCA
Antinuclear antibody (ANA)	Indirect immunofluorescence	Results are reported as negative or positive on a 1 in 80 dilution of serum applied to HEp2 cells. Staining with a serum dilution of 1:80 is considered low level positive and those at dilutions of > 1:640 are strongly positive. In addition, the following ANA patterns are reported: homogeneous, speckled, nucleolar, centromere, nuclear membrane
Anti-double-stranded DNA (dsDNA)	ELISA	Negative: < 10 U/mL Equivocal: 10–15 U/mL Positive: > 15 U/mL
Anti-cyclic citrullinated peptide	ELISA	Negative: < 7 U/mL Equivocal: 7–10 U/mL Positive: > 10 U/mL
Rheumatoid factor	ELISA	Negative: < 3.5 IU/mL Normal range: 3.5–5.0 IU/mL Positive: > 5 IU/mL
Extractable nuclear antigen (ENA) antibodies: Ro (SS-A) La (SS-B) Sm U1RNP Scl-70 Jo-1 Centromere B	ELISA	Results are reported as negative or positive
Intrinsic factor antibody	ELISA	Negative: < 7 U/mL Equivocal: 7–10 U/mL Positive: > 10 U/mL
Anti-myeloperoxidase antibody	ELISA	Negative: < 3.5 IU/mL Equivocal: 3.5–5.0 IU/mL Positive: > 5.0 IU/mL
Anti-proteinase 3 antibody	ELISA	Negative: < 1.9 IU/mL Equivocal: 1.9–3 IU/mL Positive: > 3 IU/mL

[1] Sections of rodent liver, stomach and kidney are used as target cells for these assays. [2] Target cells for these assays are normal human neutrophils.

Laboratory reference ranges in childhood and adolescence

The levels of many analytes in blood vary due to the physiological changes that occur during growth and adolescence. Hospital laboratories may provide reference ranges that are age-adjusted or based on pubertal stage but this is not always the case. It is therefore important for the doctor requesting these tests to understand the impact of age and puberty on interpretation of the results. For example, a creatinine of 70 μmol/L (0.79 mg/dL) is perfectly normal for the majority of adults but may indicate significant renal impairment in a child. Reference ranges for hormone results are described according to the Tanner stages of puberty (see Fig. 31.5).

33.10 Analytes that may be significantly affected by growth and puberty*

Analyte	Age/Pubertal stage	Gender	Reference range
Alkaline phosphatase (ALP)	< 1 year	M, F	80–580 U/L
	1–16 years	M, F	100–400 U/L
	16–20 years	M	50–250 U/L
		F	40–200 U/L
Creatinine	< 1 year	M, F	12–39 μmol/L (0.14–0.44 mg/dL)
	1–4 years	M, F	13–42 μmol/L (0.15–0.48 mg/dL)
	4–12 years	M, F	20–57 μmol/L (0.23–0.64 mg/dL)
	12–15 years	M, F	31–67 μmol/L (0.35–0.76 mg/dL)
	15–18 years	M	39–92 μmol/L (0.44–1.04 mg/dL)
		F	34–72 μmol/L (0.38–0.81 mg/dL)
Follicle-stimulating hormone (FSH)	Prepubertal	M	< 3.0 IU/L (< 0.6 μg/L)
		F	< 3.2 IU/L (< 0.64 μg/L)
	Pubertal stage 2	M	< 6.6 IU/L (< 1.32 μg/L)
		F	< 4.1 IU/L (< 0.82 μg/L)
	Pubertal stage 3	M	0.7–5.0 IU/L (0.14–1 μg/L)
	Pubertal stages 4–5	M	1.5–6.0 IU/L (0.3–1.2 μg/L)
	Pubertal stages 3–5	F	2.5–13.5 IU/L (0.5–2.7 μg/L)
Insulin-like growth factor 1	< 7 years	M	15–349 μg/L
		F	17–272 μg/L
	8–16 years	M	67–510 μg/L
		F	59–502 μg/L
Luteinising hormone (LH)	Prepubertal	M	< 1.0 IU/L (< 0.1 μg/L)
	Pubertal stage 2	M	< 3.0 IU/L (< 0.3 μg/L)
	Prepubertal and pubertal stage 2	F	< 1.0 IU/L (< 0.1 μg/L)
	Pubertal stage 3	M	1.0–4.0 IU/L (0.1–0.4 μg/L)
	Pubertal stages 4–5	M	1.0–5.0 IU/L (0.1–0.6 μg/L)
	Pubertal stages 3–5	F	1.0–8.0 IU/L (0.1–0.9 μg/L)
17β-Oestradiol	Prepubertal and pubertal stages 2–3	M	< 75 pmol/L (< 20 pg/mL)
	Prepubertal and pubertal stage 2	F	< 100 pmol/L (< 27 pg/mL)
	Pubertal stages 4–5	M	< 130 pmol/L (< 35 pg/mL)
	Pubertal stages 3–5	F	< 150 pmol/L (< 41 pg/mL)
Testosterone	Prepubertal	M	< 0.5 nmol/L (< 10 ng/dL)
		F	< 0.6 nmol/L (< 20 ng/dL)
	Pubertal stage 2	M	< 10.6 nmol/L (< 310 ng/dL)
		F	< 1.4 nmol/L (< 40 ng/dL)
	Pubertal stage 3	M	0.4–30 nmol/L (10–870 ng/dL)
	Pubertal stage 4	M	5.6–30 nmol/L (160–870 ng/dL)
	Pubertal stage 5	M	10–30 nmol/L (290–870 ng/dL)
	Pubertal stages 3–5	F	0.4–1.9 nmol/L (10–50 ng/dL)

*Non-SI equivalents are given in brackets where appropriate.

Laboratory reference ranges in pregnancy

The levels of many analytes in blood vary during pregnancy, when many hormonal and metabolic changes occur. The standard adult reference ranges may, therefore, not be appropriate and it is important for the clinician reviewing the results to be aware of this, to enable appropriate interpretation and patient management.

33.11 Analytes that may be significantly affected by pregnancy*

	Reference range		
Analyte	**First trimester**	**Second trimester**	**Third trimester**
Alkaline phosphatase (ALP)	17–88 U/L	25–126 U/L	38–229 U/L
Packed cell volume (PCV) or haematocrit	0.31–0.41	0.30–0.39	0.28–0.40
Haemoglobin	116–139 g/L	97–148 g/L	95–150 g/L
Human chorionic gonadotrophin	4 weeks: 16–156 IU/L 4–9 weeks: 101–233 000 IU/L 9–13 weeks: 20 900–291 000 IU/L	4270–103 000 IU/L	2700–78 300 IU/L
17β-Oestradiol	690–9166 pmol/L (188–2497 pg/mL)	4691–26 401 pmol/L (1278–7192 pg/mL)	12 701–22 528 pmol/L (3460–6137 pg/mL)
Progesterone	25–153 nmol/L (8–48 ng/mL)	Not available	314–1088 nmol/L (99–342 ng/mL)
Prolactin	765–4532 mIU/L (36–213 ng/mL)	2340–7021 mIU/L (110–330 ng/mL)	2914–7914 mIU/L (137–372 ng/mL)
Thyroid-stimulating hormone (TSH)	0.60–3.40 mIU/L	0.37–3.60 mIU/L	0.38–4.04 mIU/L
Thyroxine (free), (free T4)	10–18 pmol/L 0.77–1.40 ng/dL	9–16 pmol/L 0.70–1.24 ng/dL	8–14 pmol/L 0.62–1.09 ng/dL

*Non-SI equivalents are given in brackets where appropriate.
